58 Surgical treatment of inflammatory bowel disease

Emily Finlayson, Fabrizio Michelassi

Crohn's disease, 1473
Ulcerative colitis, 1490
Indeterminate colitis, 1500

Crohn's disease, ulcerative colitis, and the rare forms of true indeterminate colitis represent a disease spectrum with protean manifestation and complications. Although as many as half of the patients with inflammatory bowel disease require at least one surgical procedure during their lifetime, the decision to operate is rarely an easy one. Such a decision should be the result of a thorough collaboration between the gastroenterologist and the surgeon, assisted by the radiologist and the pathologist. Factors to take into consideration are the age and the general conditions of the patient; the extent of the disease; the duration of the disease and the treatment offered to that point; and the specific complication in regard to the available treatment options. Once the need for surgical intervention has been established, other factors, specific to each individual presentation, must be considered to choose the most appropriate surgical procedure. This chapter addresses surgical options and their results in view of the different indications for surgical treatment of inflammatory bowel disease. Emphasis is given to new options offered by advances in laparoscopic surgery.

Crohn's disease

Crohn's disease is a heterogeneous entity, which requires individual approaches for management due to the variety of intestinal segments affected and the different clinical manifestations of the disease. The first attempt to classify patients with Crohn's disease was based on the anatomical locations of the disease [1]. Subsequently Greenstein and Greenstein [2] proposed that perforating and nonperforating presentations might separate patients into two different clinical forms of Crohn's disease. Indeed, recurrent postoperative disease usually follows the pattern of the initial presentation [2,3]. The Vienna Classification divides patients with Crohn's disease into groups based on age at diagnosis, location of involved segment, and clinical behavior (nonstricturing and nonpenetrating, stricturing and penetrating) [4]. These distinctions have proven implications with respect to medical therapy, indication for surgery, and risk of postoperative recurrence.

The majority of patients presenting with uncomplicated active disease are initially treated with medical therapy. Although medical therapy has become more sophisticated with the adoption of new biological agents, it still fails significantly to change the natural history of the disease [5,6]. Patients still tend to require surgery as time progresses: after 20 and 30 years of symptoms, 78% and 90% of patients, respectively, require surgery [7].

Indications for surgery in Crohn's disease

The chronic, unrelenting, and recurrent nature of Crohn's disease brings these patients to the attention of the gastroenterologist during the early phases of the disease [1]. In the absence of complications, the initial management is medical, until the treatment fails or a complication ensues. Table 58.1 lists the indications for surgical treatment.

A significant number of patients with perforating Crohn's disease present with septic complications as the first presentation or recurrence [2]. Not all the septic complications are

an absolute indication for surgery; rather they are a marker of a severe and aggressive form of the disease. Fistulae are identified in one-third of patients with Crohn's disease [8], but they are rarely the primary indication for surgery. Specific indications for surgical treatment include:

- enterocutaneous and enterovaginal fistulae, where the enteric drainage becomes a matter of personal embarrassment for the patient [9]
- enterovesical or colovesical fistulae, where the connection of the intestine to the genitourinary system causes repeated urinary tract infections and eventually impairment of renal function [10]
- enteroenteric fistulae that produce functional and anatomical bypass of a major segment of intestine with consequent malabsorption or profuse diarrhea.

Inflammatory masses and abscesses occur in as many as 20% of patients [8,11]. These patients should be treated with antibiotics, the abscesses drained percutaneously (if feasible), and surgery postponed until a definitive procedure can be safely performed. Primary free perforation is an unusual complication of Crohn's disease: usually the severity of the transmural inflammation leads to the formation of adhesions, which wall-off the perforation resulting in an abscess. The secondary rupture of an abscess into the abdominal cavity requires prompt surgical intervention.

Medical treatment has failed and surgery is necessary:

- when maximal medical therapy proves inadequate
- for those patients who may be asymptomatic while on maximal medical therapy, but develop recurrence of symptoms with tapering of the medications
- when the disease progresses with worsening symptoms or a complication arises while the patient is receiving maximal medical therapy
- in the presence of significant treatment-related complications, including steroid-induced Cushingoid features, cataracts, glaucoma, hypertension, aseptic necrosis of the head of the femur, myopathy, vertebral body fractures, myelosuppression, anaphylactic reaction, or growth retardation in children [12]. In one series, failure of medical therapy was the primary indication for surgery in 33.6% of patients [8].

Up to 22% of patients present to the surgeon with worsening obstipation [8]. Symptoms are caused by single or multiple strictures or a lengthy diseased segment and differ depending on the location of the disease in the gastrointestinal tract: delayed gastric emptying in gastroduodenal disease; postprandial cramps in jejunoileitis; distention, pain, and diarrhea in colonic disease; laborious defecation in perianal Crohn's disease. Intestinal obstruction, even when complete, is rarely an indication for urgent surgery. In general, it is advisable to let the obstruction, even if complete, resolve with nasogastric decompression, intravenous hydration, and medical therapy, and to postpone surgery until after resolution of the obstruction to allow for a definitive procedure (i.e., strictureplasty or resection).

Other less frequent complications requiring surgical treatment include gastrointestinal hemorrhage, cancer, and toxic megacolon. Massive hemorrhage is an extremely rare complication occurring in less than 1% of patients [1,13]. Preoperative localization studies are mandatory to minimize the length of intestine resected. Cancer has been described in the small bowel [14] and the colon [15] and in a previous strictureplasty site [16]. The risk of cancer correlates with duration of the disease and may be higher in bypassed loops. Surgery for cancer in patients with Crohn's disease follows the same oncological principles as for sporadic cancers. Fulminant colitis with or without toxic megacolon is a known entity in inflammatory bowel disease [17,18]. The surgical treatment of this complication will be discussed in more detail under "Ulcerative colitis" below.

Crohn's disease of the stomach and duodenum

Crohn's disease may involve any portion of the gastrointestinal tract, from the mouth to the anus. About 2%–4% of patients with Crohn's disease present with involvement of the stomach or duodenum [19]. The most common indications for surgical treatment include hemorrhage and obstruction [20] (Fig. 58.1). Indeed, in a review of 108 patients, 83% underwent surgery for this complication [21]. Multiple surgical procedures have been advocated for the treatment of gastroduodenal Crohn's disease. Resectional antiulcer procedures have been performed mostly in situations in which an ulcer was misdiagnosed, and they have been associated with high morbidity and mortality rates [19]. Bypass procedures, such as gastrojejunostomy with or without vagotomy, have been the procedures most often advocated. Based on the location of the disease, gastroduodenostomy or duodenojejunostomy have also been advocated. These procedures are associated with good short-term outcome and acceptable morbidity rates, although delayed gastric emptying occurs in up to 24% of patients [22], occasionally requiring reoperation [23]. Strictureplasty has been advocated as an alternative to bypass procedures in selected patients. Only two retrospective reports are available that compare strictureplasty with bypass surgery for treatment of gastroduodenal Crohn's disease [22,23]. With a follow-up of between 42 and 192 months the strictureplasty-treated group had a lesser rate of delayed gastric emptying (15% vs 24%), but suffered more anastomotic dehiscences (12% vs 6%) and had a higher rate of repeated surgical interventions: 11 of 26 patients (42%) required a second operation after strictureplasty, 9 of them due to recurrent Crohn's disease, compared with 24% in the bypass-treated group [22,23]. Based on these limited data, both bypass and strictureplasty procedures appear to have merit in appropriately selected patients.

Crohn's disease of the small bowel

The jejunum and ileum, not including the terminal ileum, are affected by Crohn's disease in 3%–10% of patients

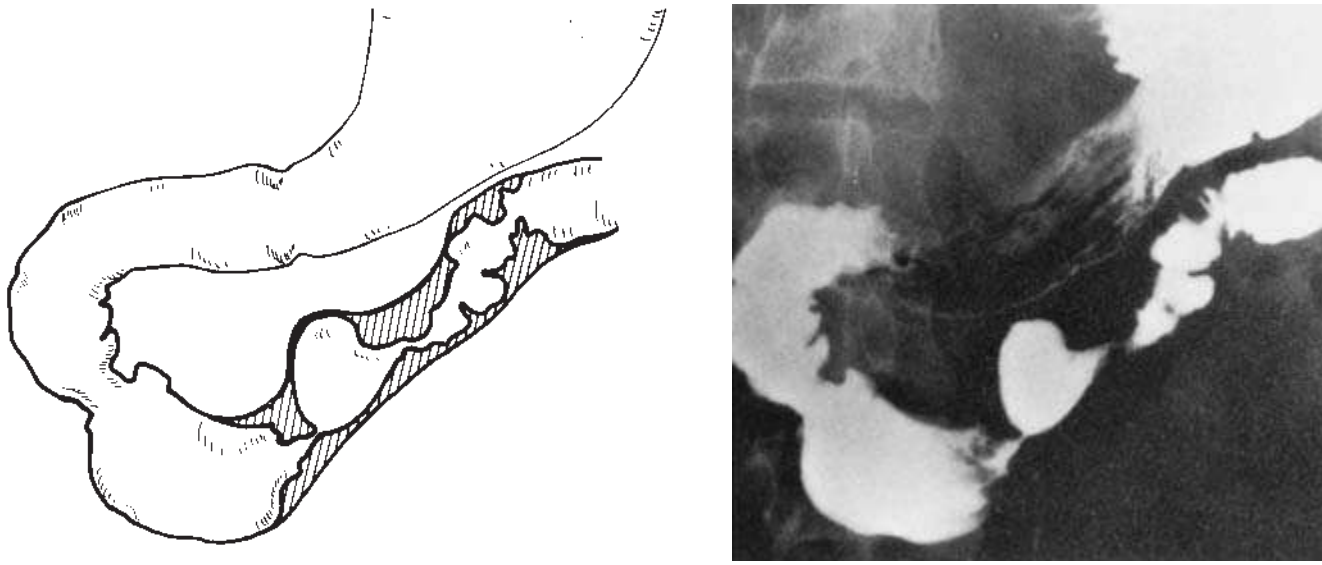

Figure 58.1 Upper gastrointestinal barium study showing Crohn's disease of the third and fourth portions of the duodenum. From Block GE, Michelassi F, Tanaka M, et al. Crohn's disease. Curr Probl Surg 1993;30:173.

[8,24]. The two most common indications for surgical treatment are obstruction and sepsis; massive hemorrhage and carcinoma are much less common. Chronic, high-grade small bowel obstruction may be caused by single or multiple, short or long strictures. These patients present with postprandial abdominal pain, nausea, and vomiting and often progress to a high-grade obstruction. When multiple tight strictures are present, the small bowel is transformed into a sequence of dilated saccular segments separated by tight, ring-like strictures (Fig. 58.2). The dilated segments, which contain partially digested food particles, become the ideal environment for bacterial overgrowth. Because of bacterial overgrowth and stagnation, patients report symptoms of occasional diarrhea, malabsorption, and vitamin B-12 deficiency.

Patients with this clinical picture have traditionally undergone resection of long segments of small bowel. Considering that Crohn's disease is a recurrent disease and up to 30% of patients require a second operation [25], short bowel syndrome may eventually be precipitated in 1.5%–12.6% of cases [26,27]. In an attempt to preserve bowel length, Lee and Papaioannou in 1982 [28], and subsequently Alexander-Williams and Haynes in 1985 [29], described the use of strictureplasty, which had been previously described in India to correct tubercular stricture of the terminal ileum and cecum [30].

Many different strictureplasty techniques have been described. The most popular are the Heineke–Mikulicz, the Finney, and the side-to-side isoperistaltic strictureplasties [31–39]. Generally for short strictures, less than 10–12 cm in length, a Heineke–Mikulicz strictureplasty is performed (Fig. 58.3); for longer strictures either a Finney type (Fig. 58.4) or a side-to-side isoperistaltic strictureplasty (Fig. 58.5) is indicated. Prior to performing a strictureplasty, it is advisable to perform biopsy on all suspicious areas to rule out the presence of malignancy. Strictureplasty is contraindicated in the presence of active sepsis (peritonitis, abscess, or acute fistula), when the bowel wall is thickened and unyielding, when the stricture has undergone malignant degeneration, or in patients with severe weight loss and marked hypoalbuminemia [40].

The Cleveland Clinic group reviewed their experience of 1124 strictureplasties in 314 patients with a median follow-up of 7.5 years [40]. The overall morbidity rate was 18%, including a 2% rate of anastomotic dehiscence and 7% postoperative bleeding from the suture line requiring transfusion [41]. These investigators reported a 34% surgical recurrence rate, which compares favorably with the results of resective surgery [42]. The authors identified age and weight loss as the only factors associated with postoperative morbidity, and younger age at diagnosis as the primary factor associated with early recurrence [40]. These results confirm the safety and efficacy of strictureplasty in selected patients. Yet, as a word of caution, one of their patients developed adenocarcinoma at the strictureplasty site 7 years after the index operation. Negative results of biopsies of the stricture had been obtained at the time of the strictureplasty [43].

Septic complications, such as an inflammatory mass, abscess, and, occasionally, fistula, are also considered indications for surgical treatment of small bowel Crohn's disease. As already discussed, fistulae usually reflect severe disease

rather than an absolute indication for surgical treatment. Septic complications are discussed in further detail under "Crohn's disease of the terminal ileum" below.

The first case of a carcinoma of the small bowel in Crohn's disease was described by Leon Ginzburg in 1956 in a case of stricturing small bowel Crohn's disease [44]. Since then there have been more than 100 cases described in the literature [16,43–51]. Most cancers are adenocarcinomas [46], but they differ from de novo cancers in many respects: they present at a younger age, are more common in the distal small bowel, and may be multifocal or diffuse [47].

Cancer may occur in association with chronic perineal fistulae and excluded loops of small bowel. Several cases of small bowel adenocarcinoma in bypassed loops have been reported [47–50]. The increased risk of cancer development in a bypassed loop and the inability to image such a loop has deterred surgeons from performing intestinal bypass or allowed them to consider leaving excluded intestinal segments in situ for a long time.

The surgical treatment of small bowel carcinomas in Crohn's disease is segmental radical resection, when feasible. The prognosis is poor, with survival rates reported between

23% at 3 years [49] and 5% at 5 years [51]. Patients with cancers in a bypassed loop usually do not survive longer than 18 months [49].

Crohn's disease of the terminal ileum

The terminal ileum is the most common gastrointestinal location requiring surgery in Crohn's disease and accounts for approximately 40% of patients with Crohn's disease referred to the surgeon [1]. Classically, patients present with obstructive symptoms or with septic features suggesting either a contained perforation or an abscess with or without a fistula. Cancer and hemorrhage are infrequent indications to surgical resection.

For obstructive disease of the terminal ileum secondary to strictures (Fig. 58.6) or an inflammatory mass (Fig. 58.7), resection is the treatment of choice. An ileocecectomy usually suffices; if the disease extends into the colon, an ileocolectomy may be necessary.

Abscesses (Fig. 58.8) and fistulae are two relatively common complications of Crohn's disease of the terminal ileum. Their occurrence may influence the timing of surgery and significantly increase its complexity. When feasible, these patients should be managed with image-guided drainage and antibiotics, with elective resection at a later time. This approach is feasible in approximately 50% of patients [52]. If percutaneous drainage is not successful or in the presence of a secondary free rupture of the abscess in the peritoneal cavity, open surgical exploration is necessary. The procedure should aim at draining the abscess, clearing the sepsis, and resecting the diseased intestinal segment. A primary anastomosis can then be fashioned if the patient's hemodynamic and nutritional conditions allow it and if the final suture line can be placed away from the abscess cavity. It is also advisable to lay an omental flap on the residual wall of the abscess cavity to quarantine any residual infection from the abdominal cavity and the anastomosis. If a primary anastomosis is not advisable, a stoma needs to be brought out as a temporary end ileostomy. When the extent of the inflammatory reaction is massive and involves several adjacent loops of bowel, the procedure should be limited to draining the abscess and placing a proximal diverting stoma. In due time, after most of the acute inflammatory reaction has subsided, a limited resection of the diseased bowel can be performed, saving a significant amount of bowel that otherwise would have been resected at the time of the first exploration.

Psoas abscess occurs as a result of a retroperitoneal perforation of the ileocecal region. Clinical manifestations vary from mild sepsis to severe psoas spasm with hip pain, flexion, and external rotation of the thigh associated with an abdominal mass. The retroperitoneal process can compress the ureter

and cause right hydronephrosis (Fig. 58.9). Resection of the inflammatory mass and drainage of the abscess usually relieves the compression on the ureter and cures the hydronephrosis.

Fistulae are common in Crohn's disease of the terminal ileum, but they rarely represent the only indication for surgical treatment. In one series of 639 patients undergoing surgery for Crohn's disease, 331 patients had disease in the terminal ileum. Of these, 217 patients (65.6%) were found to harbor 285 intraabdominal fistulae; yet these fistulae represented the primary indication for surgical treatment in only 6.3% of our patients [53]. Enteroduodenal, enteroenteric, and enterocolic fistulae usually are asymptomatic and often discovered only during a careful abdominal exploration or at inspection of the resected specimen [54]. These fistulae require surgical treatment only if they cause massive diarrhea because of the bypass of a sizable length of intestine.

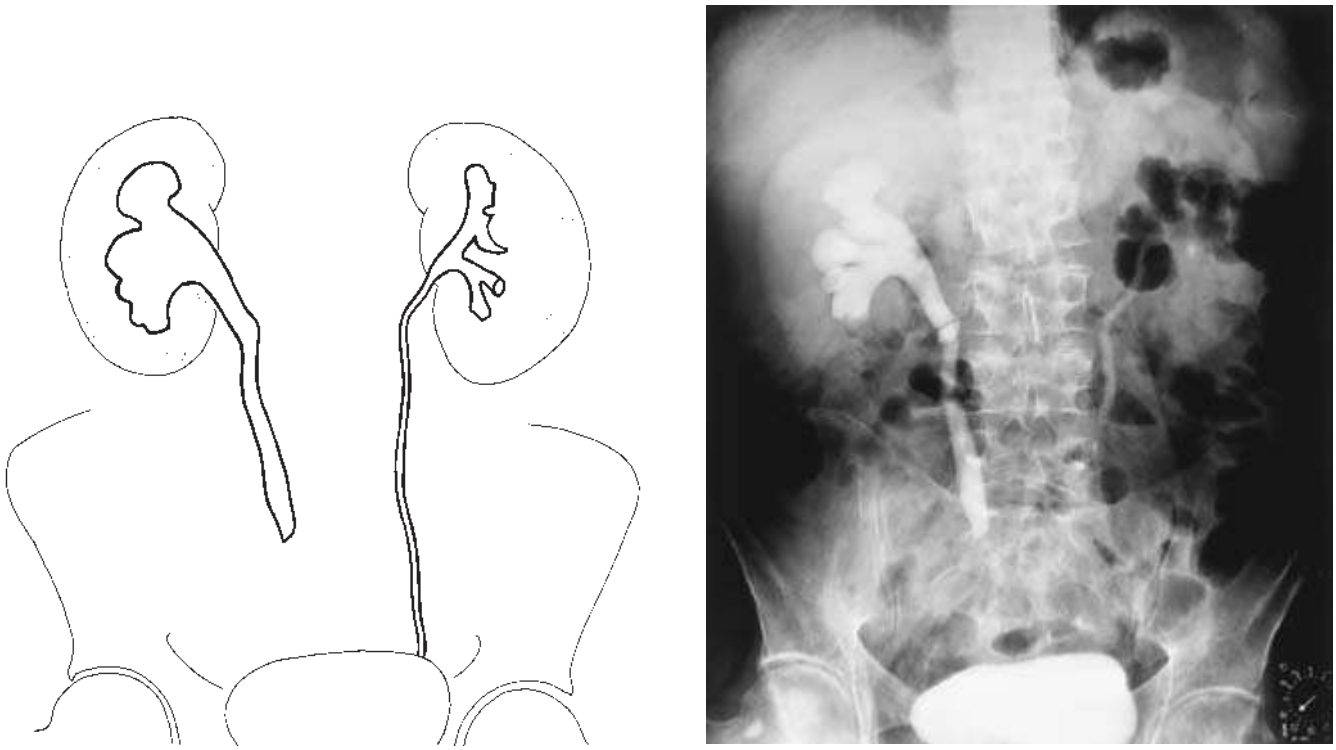

Figure 58.9 Complete right ureteral obstruction with hydronephrosis. From Michelassi et al. [8].

Enterocutaneous fistulae usually drain through a previous abdominal scar or through the umbilicus [55]. At times they result from surgical incision and drainage of a subcutaneous abscess complicating severe intraabdominal disease or from percutaneous drainage of an abdominal abscess [52]. The presence of an enterocutaneous fistula does not necessarily entail immediate surgical intervention [9,56]. Patients may be reluctant to undergo surgical treatment when the enterocutaneous fistula has a minimal output and the underlying disease is under satisfactory control. However, in most cases the difficulty in maintaining personal hygiene, the fear of social embarrassment, the bothersome symptoms associated with the severely diseased segment that led to the formation of the fistula, and the skin excoriation, which invariably forms around the cutaneous opening of the fistula, become factors in indicating the need for surgical treatment.

Enterovesical fistulae occur in 2%–5% of patients with Crohn's disease [57,58]. Some controversy exists regarding the timing of surgical intervention in the presence of these fistulae. Nevertheless, most surgeons and gastroenterologists agree that the consequences of chronic urinary tract infections on renal function, in addition to the symptoms affecting the intestinal tract itself, represent an indication for operation. Enterovaginal fistulae are rare complications of Crohn's disease and most often occur in women who have undergone a previous hysterectomy. The vaginal discharge is cause for discomfort, social and sexual embarrassment, and difficulty in maintaining personal hygiene. Most patients readily accept surgical intervention.

Massive intestinal hemorrhage is a rare complication of terminal ileitis [59]. Because the hemorrhage originates from active disease, patients with Crohn's disease are likely to have repeated episodes ultimately requiring surgical intervention. If the extent of the disease is limited, as assessed by contrast radiography, an elective resection should be considered after two episodes of self-limited hemorrhage. In the presence of an ongoing, unrelenting hemorrhage, an angiogram should be obtained to localize the source of bleeding, especially in the presence of multiple sites of disease involvement [13]. The possibility of a life-threatening hemorrhage in patients with Crohn's disease should not be underestimated. Five cases of exsanguinating gastrointestinal hemorrhage have been reported in the literature [60].

Malignant transformation of the terminal ileum is, fortunately, rare. Its treatment is based on oncological principles and it has been described in the previous section.

Controversies still persist about the timing of the operation. In view of the fact that 70%–90% of these patients require a resection in their lifetime [61,62], some authors have advocated early resection to avoid possible septic complication associated with recurrent attacks and the side effects of aggressive medical treatment [63,64]. However, in general,

most physicians and surgeons recommend a resection only after medical treatment has failed or a complication of the disease has arisen.

Overall, the results of resection are excellent. Large series have reported a surgical recurrence rate between 31% and 36% at 10 years, with 69% of patients requiring only one resection [61,63]. Several disease-related and patient-related factors associated with high risk of recurrence have been identified. The presence of perianal disease, extensive ileal involvement, and cigarette smoking seem to be significantly associated with a high recurrence rate after ileocolic resection [61,65,66]. When Crohn's disease recurs, it usually involves the ileum just proximal to the anastomosis; less frequently the colon just distal to the anastomosis or the anastomosis exclusively are involved. Strictureplasty has been used, with excellent results, for the treatment of anastomotic stricture secondary to recurrent Crohn's disease after ileocolic resection [67,68].

Crohn's colitis

The colon is affected by Crohn's disease in up to 30% of patients [1,8,69]. The involvement can be limited to a segment or extend to the entire colon and rectum; furthermore, patients may present with associated anorectal or small bowel disease. In the presence of pancolitis without perineal or small bowel manifestations of the disease, the differential diagnosis between Crohn's disease and ulcerative colitis may be difficult, and many patients end up carrying a diagnosis of indeterminate colitis as a result of diagnostic uncertainty [70] or the wrong diagnosis [71–74]. With the advent of ileoanal pouch procedures this differentiation has become crucial because pouch reconstruction in patients with Crohn's disease is contraindicated, with a pouch failure rate of up to 40% [71–74].

The most common indication for surgery in patients with disease localized primarily to the colon is failure of medical therapy [8,75]. These patients present with persistent and often bloody diarrhea and abdominal pain not responding to medical therapy. With worsening conditions, toxic colitis with or without megacolon may develop. This complication is less frequently associated with Crohn's disease than with ulcerative colitis, but it carries similar mortality rates (14%–16%) in both conditions. Factors affecting mortality include age (30% for patients older than 40 years old vs 5% for those younger than 40), gender (21% in women vs 13% in men), and the occurrence of colonic perforation (44% for cases with perforation vs only 2% in those without perforation) [18]. In the absence of overt perforation, initial therapy consists of high-dose steroids, bowel rest, and antibiotics. Lack of improvement over a short period of time or any signs of worsening condition are indications for an urgent operation to avoid colonic perforation.

There is a 4–20 times increased risk of colorectal cancer in Crohn's colitis [76,77], with an incidence between 1.4% and 1.8% [15,44–46,78,79]. Carcinoma can arise in a long-standing benign stricture, probably due to chronic inflammation [80].

Routine surveillance colonoscopy should be considered after 7–10 years of disease duration, with the recommendation to proceed with resection in the presence of dysplasia. Prophylactic colectomies should be performed for: tight strictures not allowing passage of the endoscope and, therefore, interfering with a complete colonoscopy; a stricture difficult to survey; multiple pseudopolyps rendering surveillance difficult; and, as mentioned earlier, the presence of an excluded intestinal segment (retained rectal stump). Surgery for adenocarcinoma in Crohn's colitis should be based on oncological principles and on the extent of the lumenal disease.

Septic complications occur in the form of inflammatory masses or, more infrequently, fistulae or abscesses. Inflammatory masses can be found in any segment of the colon and rectum with equal frequency. Transverse colon disease occasionally fistulizes into the stomach. A common location for abscesses to occur is the descending colon at the junction with the sigmoid colon. These abscesses, which form in the left parietocolic gutter and lie over the psoas muscle, may be confused with a complication of diverticular disease. Usually, the age of the patient and other manifestations of Crohn's disease help in arriving at the correct diagnosis.

Several different surgical approaches are available for the treatment of patients with Crohn's colitis. The surgical plan depends on the location of the disease, the urgency of intervention, the presence of complications, and the general condition of the patient. In Crohn's colitis the need to preserve bowel length is less pressing than in small bowel Crohn's disease, but still the extent of surgery should be carefully planned by the surgeon in conjunction with the gastroenterologist, the pathologist, the radiologist, and, foremost, the patient.

Surgery for Crohn's disease of the colon must encompass the entire gross disease. In patients with disease limited to the right colon, a right hemicolectomy will suffice (Fig. 58.10); if the disease extends beyond the mid-transverse colon, an extended right hemicolectomy may be necessary; for patients with disease involving the entire abdominal colon (Fig. 58.11), an abdominal colectomy will be needed. All these procedures can be performed in one stage. In the past, a diverting ileostomy was widely used as the sole initial step in patients too ill to tolerate definitive surgery [81–85]. A more contemporary approach consists of the appropriate colon resection with an end ileostomy and delayed reconstruction of the gastrointestinal continuity. This procedure is also indicated in patients with a diagnosis of indeterminate colitis to preserve the option of an ileal pouch procedure if the diagnosis of ulcerative colitis is later confirmed or established.

Abdominal colectomy and ileorectal anastomosis, in one or two stages, is ideally suited for young patients with no sigmoid or rectal involvement and normal anal sphincter function [86]. In older adult patients, the decision in favor

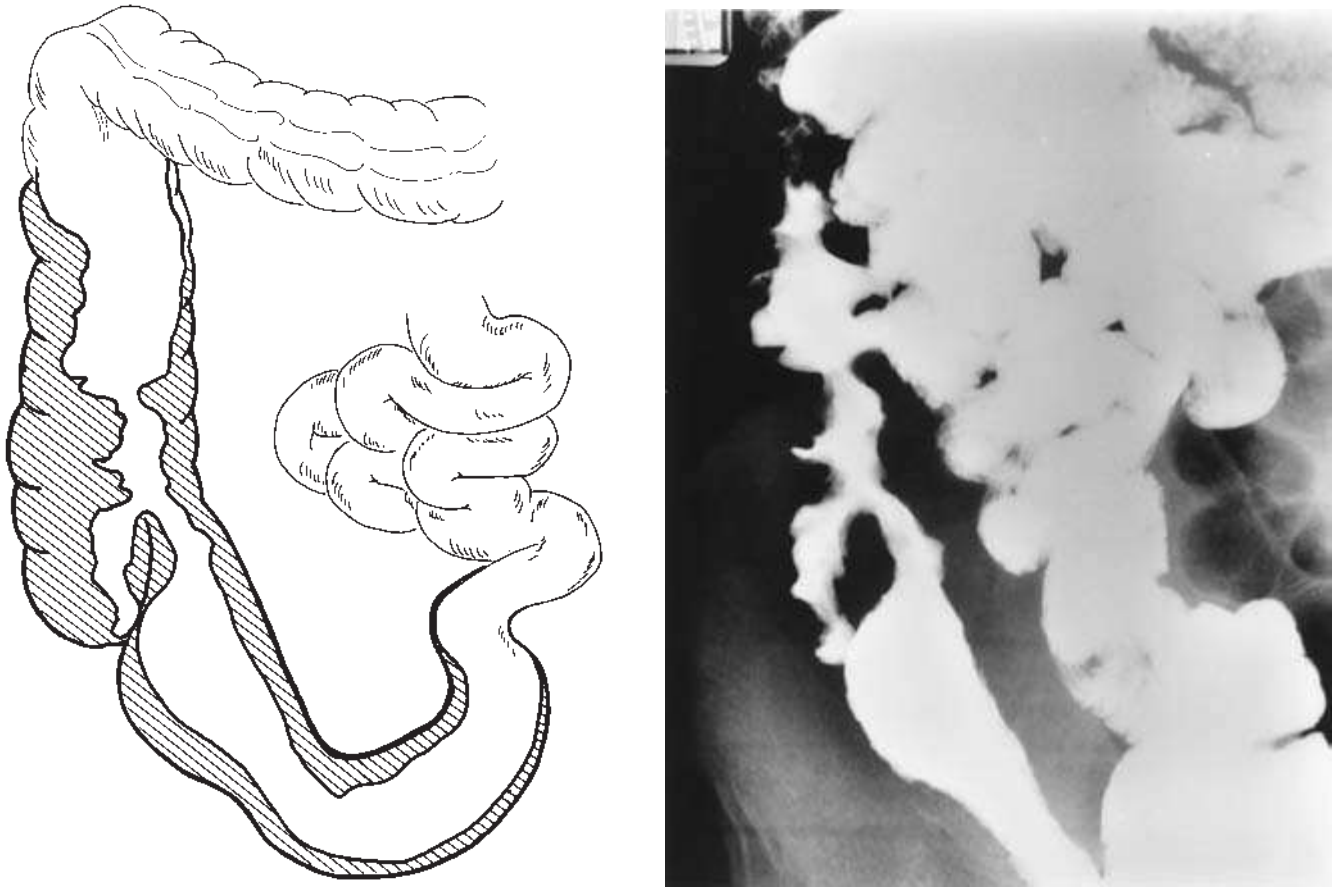

Figure 58.10 Small bowel follow-through series showing Crohn's disease of the ileal cecal valve and right colon. From Michelassi F. Crohn's disease. In Bell RH Jr, Rikkers LF, Mulholland MW (eds). Digestive Tract Surgery: a Text and Atlas. Philadelphia: Lippincott-Raven, 1996:1201.

of an abdominal colectomy with ileorectal anastomosis is a difficult one and needs careful consideration of the degree of anal sphincter function and the possible debilitating high fecal frequency.

Total proctocolectomy and end ileostomy, in one or two stages, has been and still is the surgical therapy of choice in patients with Crohn's pancolitis or in Crohn's colitis with extensive anorectal involvement or anal incontinence [87]. Recurrence of Crohn's disease in the small bowel after total proctocolectomy has been reported in 3%–46% of patients [88,89], and it involves the distal 25 cm of ileum in up to 90% of patients [90]. If Crohn's disease is limited to the rectum (Fig. 58.12) or the patient is affected by severe anorectal disease or incontinence, an abdominoperineal resection with a left-end colostomy is the procedure of choice.

In the presence of severe perineal sepsis, patients undergoing a proctocolectomy or an abdominoperineal resection are at risk of developing perineal wound problems. Large series have reported up to 34.4% of nonhealing perineal wounds after proctectomy in Crohn's disease [90–92]. A subtotal colectomy or an abdominal proctectomy with colostomy may be indicated as the first step to allow for appropriate drainage and healing of the perineal sepsis. A perineal proctectomy at a later time is still necessary to avoid the risks of a retained rectal stump. The use of myocutaneous flaps may further decrease the incidence of nonhealing perineal wounds [93].

For left-sided Crohn's colitis (Fig. 58.13), segmental resection is a valuable alternative. It allows for restoration of bowel continuity and maintenance of the absorptive mucosa of the right colon, but patients are at risk of recurrence and additional surgery [94]. Small series have reported a recurrence rate of 62% at 5.5 years, requiring further surgery [95], but up to 86% of patients maintaining bowel continuity at 14 years [96].

Ileal pouch surgery is contraindicated for patients with Crohn's colitis [72,74]. Despite the effort correctly to diagnose patients before surgery, some patients undergo surgery with a preoperative diagnosis of indeterminate colitis or ulcerative colitis and are found to have Crohn's disease on final pathological evaluation of the specimen [97]. Sagar and colleagues [98] and Deustch and associates [71], in two separate unselected series, reported a pouch failure rate of 45% at 10 years in a total of 46 surgical patients with a preoperative diagnosis of mucosal ulcerative colitis who were subse-

quently proven to have Crohn's disease. Hyman and colleagues [73] analyzed the outcome of this procedure on 25 patients: 16 patients, at a mean follow-up of 38 months, had a functioning pouch, 7 had required pouch excision, 1 had a diverting stoma, and 1 had died. Only one of nine patients with preoperative clinical features suggestive of Crohn's disease had a functioning pouch, with complications uniformly occurring within months of ileostomy closure. In contrast, 15 of 16 patients without preoperative features of Crohn's disease had maintained their pouch, generally with good results. These studies suggest that the pelvic pouch procedure should not be performed in patients with clinical features of Crohn's disease because of the high associated complication rate. Yet, there might be a subgroup of patients with Crohn's colitis who could ultimately be recognized as possible candidates for an ileal pouch procedure. To this extent Panis and colleagues [99] reported a series of 31 patients with Crohn's disease with no evidence of perineal or small bowel disease. These patients were specifically selected for ileoanal pouch as an alternative to ileostomy. Their results were compared with those obtained from patients with ulcerative colitis undergoing the same procedure. Of the 31 patients with Crohn's disease, six (19%) experienced specific complications 9 months to 6 years after surgery: three had pouch–perineal fistulae, which required pouch excision in two cases. At the 5-year follow-up, there was no significant difference between patients with Crohn's disease and patients with ulcerative colitis with a functioning pouch, in terms of stool frequency, continence, gas/stool discrimination, leak or need for protective pads, and sexual activity. It is probable that in the future more sophisticated diagnostic tests may allow selection of a subgroup of patients with Crohn's disease appropriate for ileal pouch procedures.

Perianal Crohn's disease

Anorectal Crohn's disease may manifest with edematous skin tags, fissures, ulcers, abscesses, fistulae, strictures, and, as a complication of chronic, long-standing inflammation, anal cancer. The reported incidence of perianal Crohn's disease requiring surgery varies between 25% and 34% [93,100]. Crohn's colitis is much more frequently associated with anal lesions than Crohn's disease of the small bowel (52% vs 14%). When an anal lesion is the manifesting sign, Crohn's disease will soon develop elsewhere in the intestine [100]. Because these lesions frequently herald the onset of intestinal Crohn's disease, the physician must always be aware of the possibility of inflammatory bowel disease when dealing with a suspicious anal lesion.

Skin tags, fissures, and ulcers rarely require surgical treatment. The most common indications for surgery in perianal

Crohn's disease are septic in nature. For these complications the treatment plan should be based on the patient's general condition, anal continence, and degree of colorectal involvement. In patients with a grossly normal rectal mucosa, the anal stenosis can be dilated, ischiorectal abscesses can be drained, appropriate fistulectomies can be performed, and repair of complex fistulae or low rectovaginal fistulae can be attempted with every expectation of successful outcome. In patients with mild to moderate involvement of the rectal mucosa, treatment of the rectal disease with topical anti-inflammatory agents may occasionally effect dramatic improvement. If the improvement persists, surgical repair of even complicated defects may result in complete healing and normal function. In patients with severe perineal disease or incontinence, only a proctectomy with a permanent stoma may be expected to bring relief. Extensive perineal disease, although not a sole indication for proctectomy, usually is associated with destruction of the sphincter mechanism and incontinence, often dictating a resection with a permanent stoma.

Patients presenting with an ischiorectal abscess require prompt incision and drainage. In the majority of patients, the incision will heal by secondary intention without any need for further intervention. In 35% of patients, a fistula-in-ano will develop [93].

Many surgeons mistakenly believe that perineal wounds do not heal in patients with Crohn's disease and therefore have adopted a philosophy of therapeutic nihilism even in the presence of simple fistulae-in-ano [101–105]. This attitude may result in the patient's continued suffering and may lead to the development of new abscesses and fistulae, progression to a "watering-pot" perineum, and destruction of the sphincter mechanism. Patients with Crohn's disease with symptomatic low anal fistula involving minimum sphincter musculature can be treated safely with fistulotomy [106], with healing rates up to 85% [107,108]. In patients with horseshoe abscesses and high fistulae, aggressive local surgical intervention aimed at drainage of sepsis and appropriate usage of setons permit preservation of the sphincter and good postoperative function [106,107,109,110].

Rectovaginal fistulae occur as a complication of anorectal Crohn's disease in about 10% of patients [111,112] and require special mention. Most fistulae are truly anovaginal, with the internal opening located at the dentate line. These fistulae result from deep anterior anal ulceration and less commonly from a cryptoglandular source. These patients may be treated with a mucosal advancement flap [113–115]. This procedure entails performing a semicircular incision at the dentate line, with the internal opening of the fistula at its center (Fig. 58.14). A 3–4-cm flap of mucosa, submucosa, and smooth muscle is elevated in a proximal direction. The tract is curetted and closed and the flap is advanced to the anoderm and sutured without tension. Several variations have been proposed when the rectal mucosa is significantly diseased, including performing the repair from the vaginal side [116,117] and using an anocutaneous flap from the perianal skin [118]. Success rates with this approach have been reported around 70%–75% in relatively small series [113–115]. In the event of a failure, the advancement can be repeated, as reported by Joo and colleagues [115]. In their series, four of five patients who did not heal with the first procedure were successfully closed after a second attempt.

Anorectal complications also include stenosis and cancer. In the absence of severe rectal disease, anal stenosis can be dilated to achieve prolonged symptomatic relief. Cancer may develop from the diseased anorectal mucosa, a chronic fistula-in-ano, or a retained rectal stump. In all cases, an oncological resection needs to be carried out. In the presence of a resulting large soft tissue and cutaneous perianal defect, the use of myocutaneous flaps may be the only way to achieve primary closure of the perineal wound (Fig. 58.15).

All told, an aggressive surgical approach should allow healing of the Crohn's disease perineal septic complication with sphincter preservation in 62%–86% of patients [112,119]. In our series of 224 consecutive patients, the reasons for proctectomy in 85 patients included aggressive disease not responding to conservative measures in 66 patients, extensive fistular disease in 15 patients, fecal incontinence in 2 patients, and tight anal stenosis in 2 patients. We found that patients with rectal disease had a significantly higher rate of proctectomy than patients with rectal sparing (77.6% vs 13.6%), and that in the absence of rectal involvement, patients with multiple complications had a significantly higher rate of proctectomy than patients with single complications (23% vs 10%) [119].

Laparoscopic surgery for Crohn's disease

Laparoscopic techniques have become standard approaches to the treatment of several upper abdominal pathologies (i.e., gallbladder disease and reflux esophagitis) and several colorectal conditions (i.e., diverticulitis, colectomies for polyps and cancer, endometriosis involving the intestine). Many of the unique features of Crohn's disease, such as the intense inflammation, thickened mesentery, enteric fistulae, inflammatory masses or abscesses, and the multiplicity of areas of intestinal involvement, have deterred some surgeons from considering a laparoscopic approach. The natural history of the disease, however, often leads to the need for repeated operations, and a less invasive approach is appealing. Additionally, patients are generally young and interested in undergoing procedures that involve minimal scarring and prompt recovery. Numerous early clinical reports described laparoscopic-assisted resections in Crohn's disease as safe and feasible [120–127].

Laparoscopic-assisted ileocolic resection (Fig. 58.16) is the most commonly performed laparoscopic procedure for Crohn's disease [120,125]. Laparoscopic fecal diversion and closure of stomas may obviate a laparotomy and allow for a

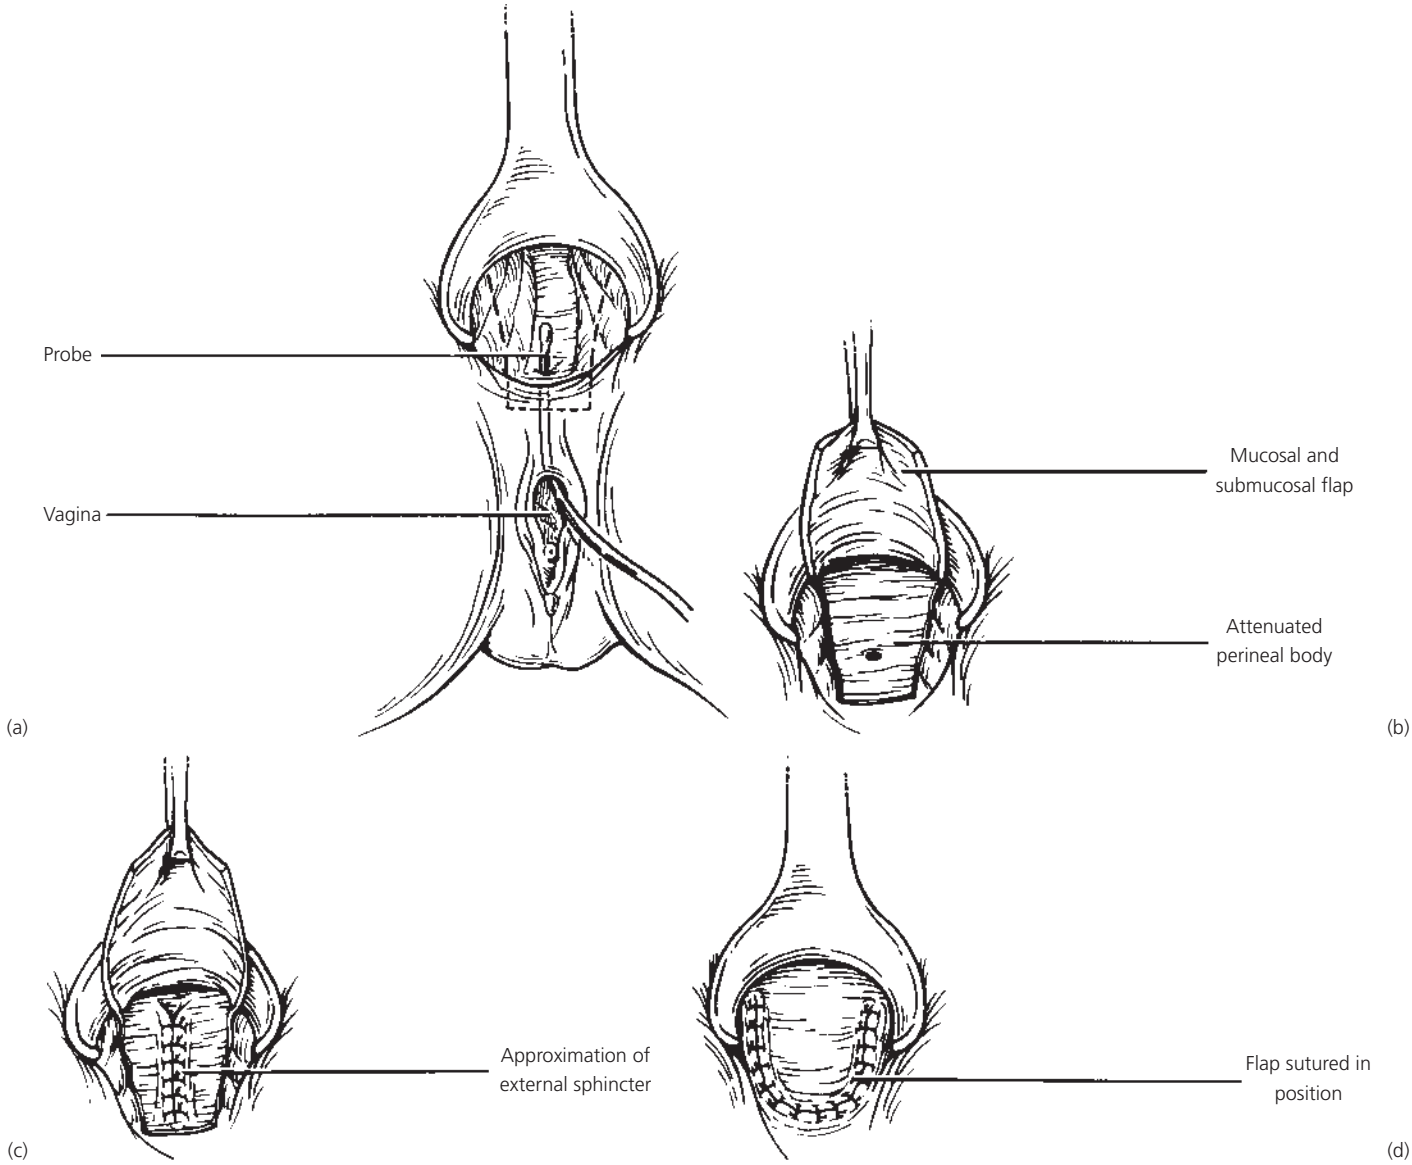

Figure 58.14 Endorectal advancement flap for low rectovaginal fistula. **(a)** The patient is in the jack-knife prone position and the probe identifies the rectovaginal fistula. **(b)** The rectal wall is elevated from the external sphincter, starting at the dentate line. **(c)** Plication of the external sphincter with closure of fistula. **(d)** The rectal wall flap is advanced over the plicated external sphincter; the tip of the flap with the fistula opening is excised; the flap is then sutured in position with interrupted sutures. full evaluation of the gastrointestinal tract. Laparoscopic-assisted small bowel resection or strictureplasty may be performed as the index procedure or when associated with another bowel resection, usually an ileocolic resection. The diseased area or areas can be marked with intracorporeal sutures, exteriorized through a small abdominal incision needed for removal of the resected specimen, and the strictureplasty performed extracorporeally in a standard fashion. Segmental or total colectomies with or without anastomosis can be performed by the laparoscopic-assisted method.

Several studies from tertiary referral centers have reported improved outcomes and reduced costs with laparoscopic ileocolic resection [127–130]. A prospective randomized trial comparing open and laparoscopic-assisted ileocolic resections in 60 patients [128] showed a faster postoperative recovery of respiratory function (measured as recovery of 80% of forced expiratory volume and forced vital capacity), a lower incidence of minor complications, and the need for a shorter abdominal incision in the laparoscopic-limited group. With a follow-up of 20 months there were no recurrences in either group.

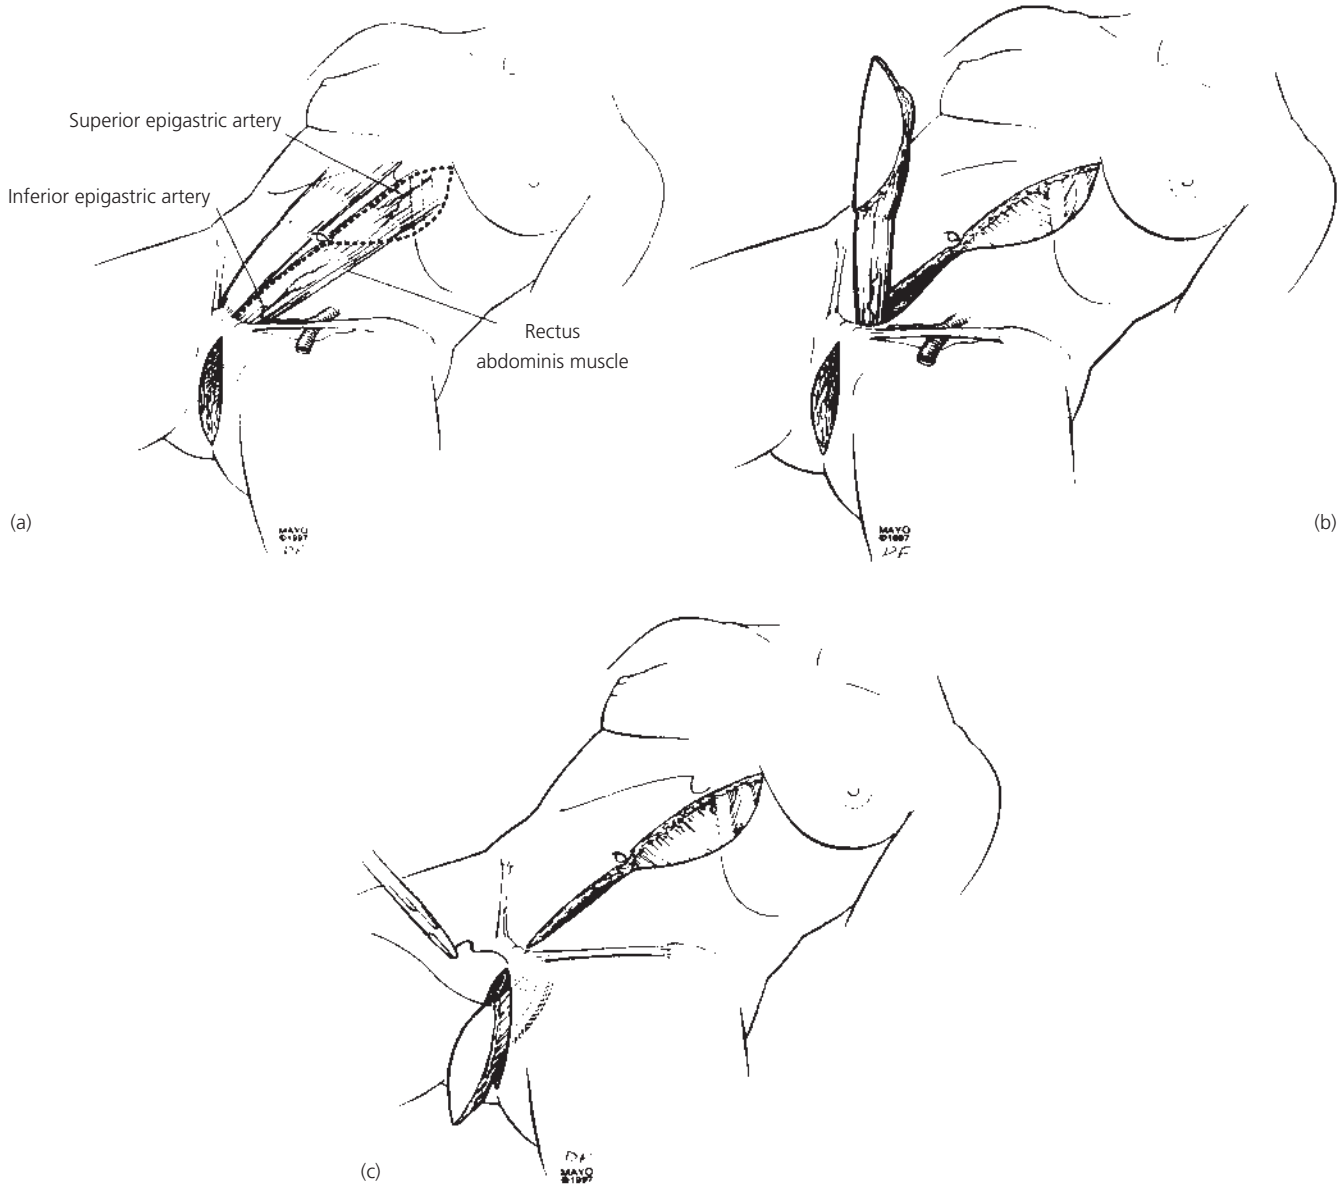

Figure 58.15 **(a)** The superior epigastric vessels supply the rectus abdominis myocutaneous flap. **(b)** The flap includes skin, anterior fascia, and the rectus muscle. **(c)** The flap is delivered through the pelvis to the perineal defect. Primary myocutaneous flap closure following resection of locally advanced pelvic malignancies. Surgery 2001;130:767; originally from Radice E, Nelson H, Mercill S, et al., Br J Surg 1999;86:349.

Case-matched retrospective studies have also shown small but measurable advantages for the laparoscopic approach [129,130]. In an analysis of 66 patients undergoing laparoscopic or open ileocolonic resection, Young-Fadok et al. [129] found that patients undergoing laparoscopic resection had a more rapid return of bowel function, shorter duration of narcotic use, and shorter hospital stay (4 days vs 7 days). In addition, costs – both direct and total – were significantly lower in the laparoscopic group. A metaanalysis of randomized and nonrandomized studies comparing open and laparoscopic surgery for Crohn's disease found in pooled analysis that whereas operative times were an average of 27 minutes longer in the laparoscopic group, laparoscopy resulted in improved short- and long-term outcomes. Patients undergoing laparoscopic resection had a faster return of bowel function, shorter hospital stay, fewer postoperative bowel obstructions, and decreased surgical recurrences [131]. Whether these results can be reproduced outside specialized centers is unclear.

In summary, laparoscopy in Crohn's disease may allow for faster recovery and reduced surgical trauma; morbidity

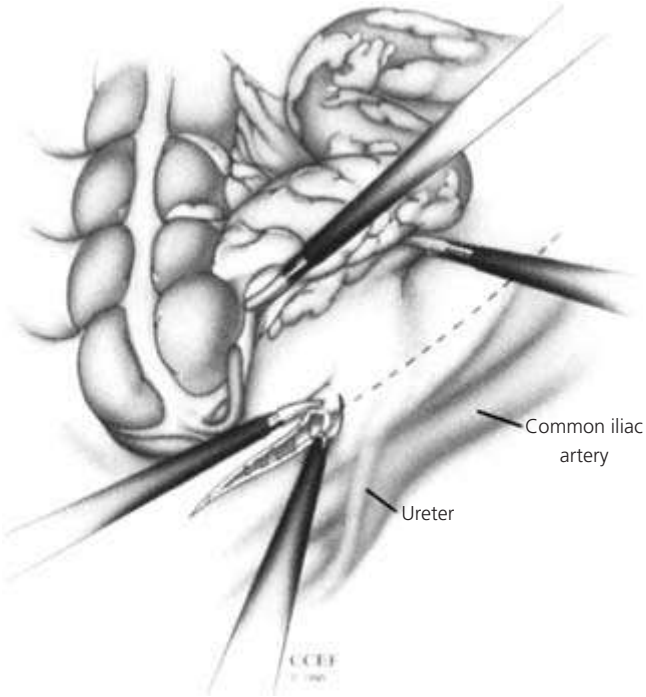

Figure 58.16 Laparoscopic ileocecectomy. From Kim SH, Milsom JW. Laparoscopy in inflammatory bowel disease. In: Michelassi F, Milsom JW (eds). Operative Strategies in Inflammatory Bowel Disease. New York: Springer-Verlag, 1999:326.

associated with laparoscopy performed by experienced hands compares favorably with the conventional open approach. With the continual improvement of laparoscopic instruments and the refinement of laparoscopic surgical techniques, this approach will likely be used increasingly in patients with more challenging and extensive complications of Crohn's disease.

Ulcerative colitis

There is a major difference between the management of ulcerative colitis and Crohn's disease. In Crohn's disease the surgical approach is palliative, with the more limited objectives of relieving the complications of the disease to improve the patient's clinical status and preserving bowel length. In ulcerative colitis, removal of the colon and rectum eliminates and cures the disease.

Ulcerative colitis is a disease confined to the colon and rectum and the presence of intestinal involvement outside these boundaries must be ruled out to confirm the diagnosis. Anamnestic evidence of recurrent episodes of perianal sepsis or bowel obstruction should suggest the possibility of Crohn's disease. On physical examination, the presence of active perianal sepsis and fistulae, healed scars, or anal stenosis should raise doubts about the diagnosis of ulcerative colitis. A complete preoperative evaluation should include: stool cultures to rule out an infectious etiology; small bowel radiographic series to exclude involvement of the small intestine; and colonoscopy to evaluate the extension of the disease, rule out the presence of malignancy, and obtain histological confirmation.

The majority of patients with ulcerative colitis present with bloody diarrhea, urgency, and fatigue; during an acute flare, they may present with fever and, possibly, abdominal distention. In absence of absolute indications for immediate surgery, such as perforation or carcinoma, the patient is treated initially with medical therapy [132–134]. However, a definitive treatment plan should be formulated after complete diagnostic evaluation, taking into account the extent and duration of the disease, the presence of dysplasia or cancer, medical therapy used, presence of side effects due to the medical treatment, and the patient's general condition and expectations. As in Crohn's disease an optimal treatment plan requires input from the patient as well as the surgeon and the gastroenterologist, assisted by the radiologist and pathologist.

Indications for surgery

The most common indication for surgical treatment of ulcerative colitis in our experience is the failure of medical therapy [135], as in the following scenarios:

- when maximum medical therapy proves inadequate
- patients who may be asymptomatic while on maximum medical therapy, but develop recurrence of symptoms with tapering of the medications
- when the disease progresses with worsening symptoms while the patient is receiving maximum medical therapy
- when the patient develops significant treatment-related complications.

Other indications for surgical treatment include the presence of a mass at colonoscopy, dysplasia on colonic biopsy, and dysplasia-associated lesions or masses (DALM). Colonoscopic detection of mucosal dysplasia is considered the best available surveillance tool for the detection of cancer. The presence of dysplasia has been reported in a much higher percentage of specimens of ulcerative colitis complicated by cancer than in ulcerative colitis without malignant transformation. Because the correlation between dysplasia and cancer is not constant, when dysplasia is found on surveillance colonoscopy, some suggest immediate colectomy, whereas others opt for continued surveillance. Gorfine and colleagues [136] reviewed the pathology reports of 590 patients who underwent total proctocolectomy or restorative proctocolectomy for ulcerative colitis and found that cancers were significantly more common among specimens with dysplastic changes. Specimens with dysplasia of any grade were 36 times more likely to harbor invasive carcinoma. Stage III disease was found in association with indefinite or low-grade dysplasia in 19.2% of cases. More important, tumor stage did

not correlate with dysplasia grade. These investigators concluded that although dysplasia is an unreliable marker for the detection of synchronous carcinoma, when dysplasia of any grade is discovered at colonoscopy, the probability of a coexistent carcinoma is high. Many believe that a histopathological diagnosis of dysplasia is an indication for colectomy.

Carcinoma was the indication for surgery in 2% of patients in one series [135]. Patients with ulcerative colitis are known to have an increased risk of colorectal cancer [137,138]. The risk of cancer increases with the extent and the duration of the colitis. Gyde and associates [139] reported an overall eight-fold increase in the risk of cancer in these patients, with a four-fold increase in the left-sided colitis and proctitis group and a 19-fold increase in the pancolitis group. In addition, the pancolitis group had a cumulative risk of 7.2% at 20 years and 16.5% at 30 years from diagnosis.

Acute fulminant colitis with or without an acute abdomen develops in about 13% of patients [139]. About 60% of these patients fail to respond to medical therapy [132,140] or develop persistent abdominal pain, distention, diffuse abdominal tenderness, rebound tachycardia, and fever, suggesting an acute abdomen. The acute abdomen may be due to the development of a toxic megacolon or a walled-off or free perforation. These patients should undergo emergency surgical intervention after appropriate volume resuscitation.

Massive hemorrhage is also another indication for urgent surgery. Persistent hemorrhage despite maximal medical treatment is a manifestation of severe disease. The hemorrhage originates from extensive mucosal ulcerations, rather than a definite arterial source. As such, an abdominal colectomy is necessary to remove the majority of the bleeding surface. A primary anastomosis should be avoided in favor of an ileostomy and closure of the rectal stump. With fecal diversion obtained by placing the ileostomy, postoperative rectal bleeding is rare. When it happens it usually responds to increased doses of systemic steroids, or administration of topical steroids or intrarectal tamponade with gauzes soaked in a diluted epinephrine (adrenaline) solution. Retention of the rectal stump maintains the option of a subsequent restorative procedure.

Proctocolectomy with Brooke ileostomy

Proctocolectomy with Brooke ileostomy was the gold standard for the treatment of ulcerative colitis until the early 1980s when Utsonomiya popularized the ileo pouch–anal anastomosis [141]. Since then the role of proctocolectomy with Brooke ileostomy in the surgical treatment of ulcerative colitis has become more limited, although it is still valuable in selected patients [142]. By removing all diseased epithelium, a proctocolectomy cures patients of the disease, eradicates the risk of malignancy associated with it, and eliminates the need for costly medications and time-consuming lifelong follow-up. The disadvantages of this operation include the presence of a permanent ileostomy, the potential for nerve injury during pelvic dissection, and the risk of perineal wound healing problems, albeit significantly less than in Crohn's disease.

A proctocolectomy is indicated in patients who are not candidates for an ileal pouch–anal anastomosis or a Kock pouch, either because of advanced age, the presence of poor anal sphincter function, or obesity. The operation may also be indicated if other medical problems make a more complex, longer operation too risky [143], or in the presence of a low rectal cancer in need of resection of the anal sphincter. Finally, proctocolectomy should be considered in patients who desire a single operation for cure or whose work makes it easier to handle an appliance rather than frequent bowel movements. There are no absolute contraindications to this procedure, although, in the emergent setting, it is advisable to stage the procedure with an initial abdominal colectomy. This strategy avoids the morbidity associated with the rectal dissection, which can be potentially difficult and time consuming in an unstable patient, and maintains the option of an ileal pouch–anal anastomosis as a second stage.

Preoperatively, the surgeon is well advised to have a thorough discussion with the patient so that the latter has a full understanding of this procedure and its implications on body image and self-perception. In addition, a stoma therapist, in charge of the postoperative care of the stoma, should mark the abdominal site for the ileostomy (Fig. 58.17). The appropriate site is the least inconvenient for the patient – generally away from bony prominences and previous scars, and not prone to interfere with the patient's clothing. The site is usually just lateral and inferior to the umbilicus midway between the midline and the right anterior iliac spine.

The proctocolectomy is associated with low postoperative morbidity. Delayed healing or nonhealing of the perineal wound is rare if the perineal dissection is performed in the intersphincteric plane, between the internal and external anal sphincter. Primary closure is associated with an 80%–90% success rate [144–146]. In the event of perineal wound infection, drainage of the wound abscess and debridement usually are sufficient for secondary healing. Rarely, myocutaneous flaps or skin grafts are necessary to achieve closure of the perineal wound. Impotence is reported in 2%–3% of male patients after proctectomy for benign disease [146,147]. Impotence is secondary to injury of the autonomic nerves during pelvic dissection, and its occurrence is minimized by keeping the dissection close to the rectum and by choosing an intersphincteric plane for the most distal anorectal resection. In women, dyspareunia may occur due to the posterior displacement of the vagina. Fortunately, it is usually temporary [146,147]. Late complications are largely related to the stoma and include retraction, prolapse, parastomal hernia, bleeding, stenosis, and varices. They usually require surgical revision. Other late complications are intestinal obstruction, urinary stone formation, and gallstone formation.

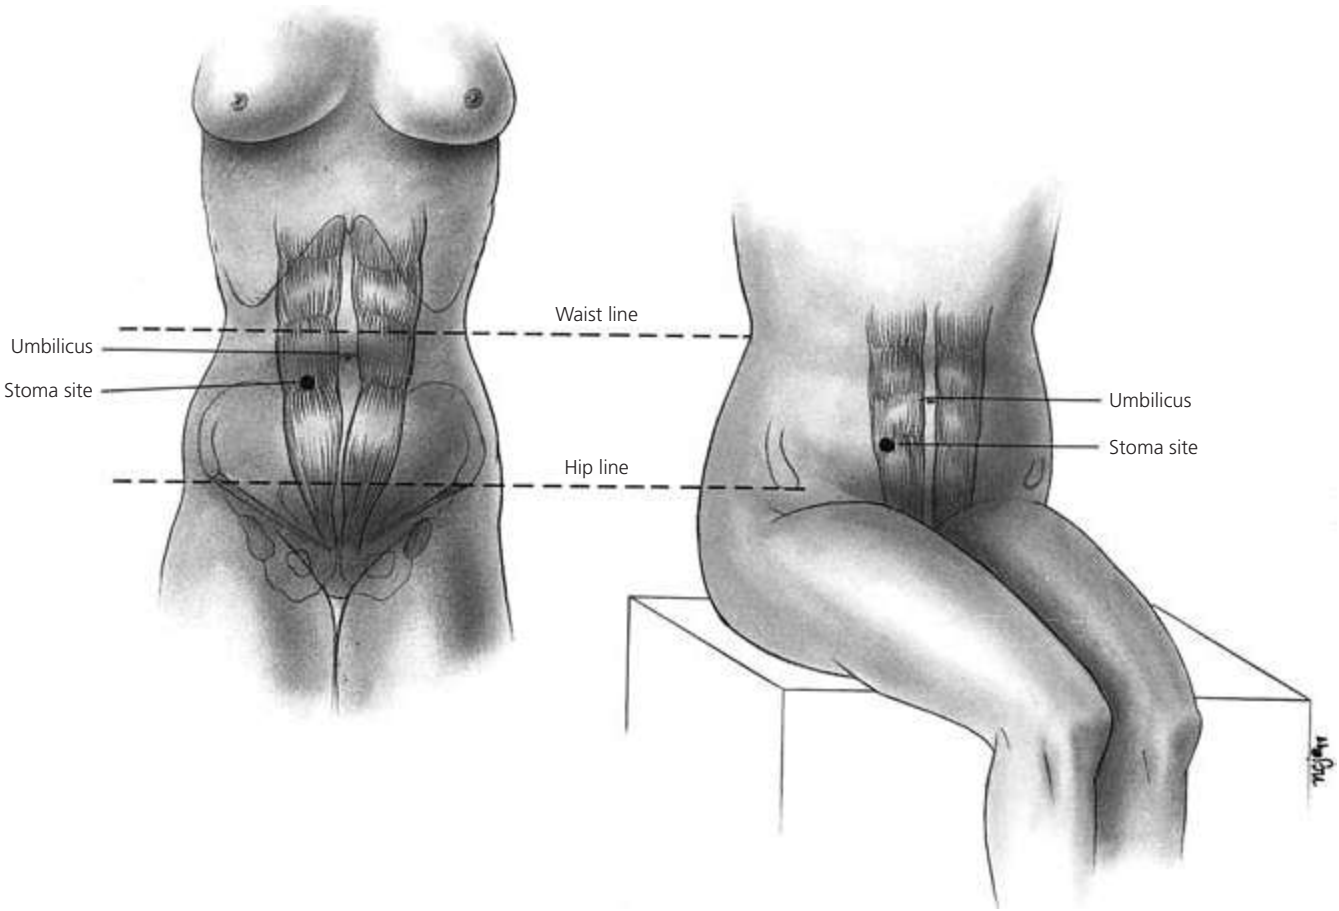

Figure 58.17 The stoma site is marked prior to surgery. The ileostomy should be located over the right rectus abdominis muscle on a flat area away from skin folds and bony prominences. From Hurst R. Proctocolectomy with ileostomy, abdominal colectomy with ileostomy, and abdominal colectomy with ileoproctostomy. In: Michelassi F, Milsom JW (eds). Operative Strategies in Inflammatory Bowel Disease. New York: Springer-Verlag, 1999:157.

Restorative proctocolectomy with ileal pouch–anal anastomosis

Most patients with ulcerative colitis who are candidates for elective operation are suitable for proctocolectomy with ileal pouch–anal anastomosis. Exceptions include patients with low rectal cancers, patients with fecal incontinence, or patients who, for work-related or personal reasons, prefer not to have a pouch [143].

Obesity is considered a relative contraindication. A fatty ileal mesentery may cause the pouch to be rather bulky and ill fitting in a narrow pelvis; furthermore, the ileal pouch may not reach the upper anal canal despite operative techniques designed to lengthen the ileal mesentery [148]. A stapled ileoanal anastomosis, as described later in the chapter, offers advantages over a conventional hand-sewn anastomosis in these challenging patients. Alternatively, patients may need to undergo an initial colectomy with ileostomy to allow for cessation of steroid therapy and a successful weight reduction program.

The presence of cancer of the colon or proximal rectum does not rule out the possibility of an ileal pouch–anal anastomosis, provided that the cancer can be completely resected during the operation [149–152]. In the presence of metastatic cancer and a short life expectancy, less extensive procedures, such as colectomy and ileorectal anastomosis or Brooke ileostomy should be considered. The Mayo Clinic group presented their experience with 77 patients with carcinoma complicating ulcerative colitis. Although pouch failure was more common in patients with cancer than in the overall registry (16% vs 7%), there were no differences between cancer and noncancer groups in operative complications, median stool frequency, incontinence, pad usage, or pouchitis [149]. A study from Toronto that reviewed function and quality of life after ileal pouch–anal anastomosis for colitis-associated neoplasia confirmed the functional results reported by the Mayo Group and showed that quality of life of these patients is excellent and equal to that of patients who have a pouch for failure of medical therapy [149].

Patients with sclerosing cholangitis and cirrhosis are at increased risk of chronic pouchitis and pouch loss after an ileal pouch–anal anastomosis, but the operation usually can be performed successfully and with morbidity rates similar

to that in patients without hepatobiliary complications of ulcerative colitis.

In the past, patient age exceeding 50 years was considered a contraindication to the procedure. However, this is no longer true. The clinical results in fit patients over the age of 50 are similar to those in younger patients [153–157]. Takao and colleagues [156] have shown that there are no significant differences among age groups relative to manometric results, frequency of bowel movements, incontinence scores, or overall patient satisfaction. The same results were confirmed by others [153,155]. Jorge and associates [154] showed that the effect of ileoanal reservoir on anal sphincter function in patients older than 50 years is similar to that in younger patients. Although impairment of internal anal sphincter function is more pronounced after ileoanal reservoir in older patients, this appears to be transient, as it is in younger patients.

Although there are small series showing that an ileal pouch–anal anastomosis is feasible in fulminant ulcerative colitis [158], most patients with emergent indications to surgical treatment should undergo an initial colectomy with ileostomy followed by ileal pouch–anal anastomosis [159] several months later.

The ileal pouch–anal anastomosis is most commonly performed in two stages. The colon and the rectum are excised to the pelvic floor, an ileal pouch is constructed with the terminal ileum (Fig. 58.18), an ileal pouch–anal anastomosis is constructed, and a diverting loop ileostomy is fashioned. The loop ileostomy is closed at a second operation about 3 months later. The operation, or portions of it, can be accomplished by using laparoscopic techniques.

Occasionally a diverting ileostomy can be omitted after construction of the ileal pouch. Omitting this transforms an elective ileal pouch–anal anastomosis into a single-stage procedure and avoids the need for a third stage in those patients who underwent an initial colectomy and ileostomy in the emergent setting or in elective circumstances (indeterminate colitis, obesity).

Several large series examining complications and long-term outcome have been published [160–163]. The Cleveland Clinic group reported their experience with 1005 ileal pouch–anal anastomoses, 858 of which had been performed for ulcerative colitis [161]. One death (0.1%) was reported, related to pouch necrosis and sepsis. The overall morbidity rate was high, with 630 patients (62.7%) suffering 1218 complications. Septic complications and reoperation occurred in 6.8% and 24%, respectively. The ileal pouch was removed in 34 patients (3.4%) overall, but in only 15 patients (1.8%) with ulcerative colitis. Approximately 25% of patients developed pouchitis. Functional results and quality of life were good to excellent in 93% of patients. The Mayo Clinic series [160,163] of more than 1300 patients showed similar results. Three patients died as a consequence of the procedure. Postoperative pelvic sepsis rates decreased from 7% in the 1981–85 period to 3% in the 1991–94 period. After mean follow-up of 6.5 years, the mean number of stools was five during daytime and one at nighttime. Frequent daytime and nighttime incontinence occurred in 7% and 12% of patients, respectively, and did not change over a 10-year period. The cumulative probability of suffering at least one episode of clinical pouchitis was 18% and 48% at 1 and 10 years, respectively, and the cumulative probability of pouch failure at 1 and 10 years was 2% and 9%, respectively [163]. The most common

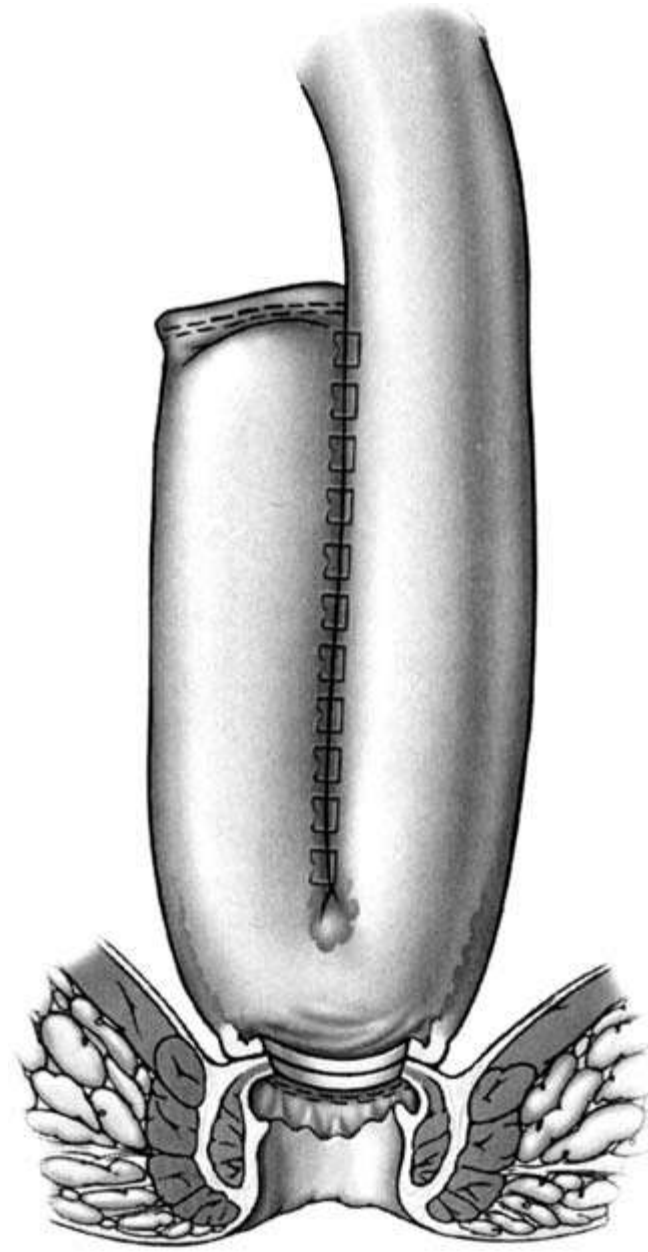

Figure 58.18 Stapled J-pouch ileoanal anastomosis. From Michelassi F, Takanishi D, McLeod RS, et al. Ileal reservoirs. In: Michelassi F, Milsom JW (eds). Operative Strategies in Inflammatory Bowel Disease. New York: Springer-Verlag, 1999:186.

early postoperative complications were bowel obstructions (13%), pelvic sepsis (5%) and wound sepsis (3%), transient urinary dysfunction (7%), and large enteric losses from the temporary loop ileostomy. Postoperative impotence and retrograde ejaculation was noted in up to 3% of men; transient dyspareunia occurred in 11% of patients after operation [160]. Pregnancy and delivery are well tolerated by women with a pouch [160].

Late complications of the procedure include: anal fistulae and abscesses, which may need drainage and possibly temporary fecal diversion; stricture of the anastomosis, which can be repeatedly dilated or treated with pouch advancement in presence of dense scar tissue or inflammation of the mucosal cuff; and pouchitis, which is the most frequent late complication. Patients with pouchitis present with abdominal cramps, frequent watery stools, urgency, incontinence, malaise, and fever. Of 120 patients who underwent ileal pouch–anal anastomosis for ulcerative colitis at the University of Chicago, 50 suffered at least one episode of pouchitis. Two-thirds of patients had multiple episodes. Chronic pouchitis occurred in six patients, necessitating pouch removal in two [164]. In a prospective evaluation of 149 patients in Sweden [165], the risk of pouchitis was highest during the initial six postoperative months. The cumulative risk leveled off after 2 years but was substantial (51%) at 4 years. Similar to our data and those of the Mayo Clinic, fewer than 10% of the Swedish patients had severe chronic pouchitis, and only two patients (1.3%) had their pouch removed because of pouchitis.

The etiology of pouchitis remains unknown. It may be due to bacterial overgrowth secondary to poor pouch emptying, or to an immunological reaction to bacterial products or a chemical injury; ischemia and reperfusion injury has also been postulated; or it may be a novel manifestation of inflammatory bowel disease. Patients who are positive for antineutrophil cytoplasmic antibody (ANCA) are more likely to develop pouchitis than those who are not [166]; also, patients with primary sclerosing cholangitis and extraintestinal manifestation of ulcerative colitis are at a higher risk of developing pouchitis, especially of the chronic type [167]. Backwash ileitis, however, does not predispose to pouchitis. Pouchitis is rare in patients who have undergone ileal pouch–anal anastomosis for familial polyposis, an observation that seems to suggest that whatever causes colitis may predispose to pouchitis.

The activity of pouchitis can be scored using a Pouchitis Activity Index [168], which uses clinical, histological, and endoscopic criteria. The activity index may help with the medical treatment of pouchitis, which is based on oral antibiotics (metronidazole and ciprofloxacin) in the majority of cases. Interestingly, smoking seems to prevent pouchitis [169].

The risk of cancer in the ileal pouch is unknown. Although no reports have appeared describing the development of carcinoma in the mucosa of a pelvic pouch, the pouch mucosa undergoes structural transformation: initially the mucosa appears normal or with mild villous atrophy and, possibly, mild inflammation. Then the mucosa shows transient atrophy with temporary moderate inflammation followed by normalization of architecture. Finally, it develops a pattern of persistent atrophy with severe inflammation [170]. These changes can progress to dysplasia [171,172]. The continual contact with a noxious medium and changes in bacterial flora are hypothesized as causes of these phenomena. The large number of proliferating cells and the frequent presence of inflammation provide fertile ground for carcinogenesis. Pouch surveillance is probably indicated, as the natural history of the pouch mucosal change remains unknown.

Controversies in ileal reservoir surgery

The technique of restorative proctocolectomy and ileal pouch–anal anastomosis for adult patients was originally described by Parks and Nicholls [173] and Utsunomiya and colleagues [141]. Since these initial descriptions several modifications have been introduced into clinical practice; these mainly involve the configuration of the pouch and the method of anastomosing the pouch to the anal canal (Table 58.2).

In the initial description by Parks and Nicholls [173], the ileal reservoir was fashioned as a triple-loop S-pouch (Fig. 58.19) with a 5-cm-long exit conduit, which created problems with evacuation. Subsequently the limb was shortened to less than 2 cm with significant functional improvement [174]. The two other pouch designs that are in use are the double-loop J-pouch [141] and the quadruple-loop W-pouch [175,176]. The lateral isoperistaltic H-pouch (Fig. 58.20) is no longer used and it is of historical interest only [177]. Each pouch design has its own advantages, and no single configuration is ideal for every patient. The S-pouch with the long exit limb allows for further reach in tall male patients with short mesentery [178]. The W-pouch (Fig. 58.21) has larger capacity and better compliance [175] and is ideal when part of the terminal ileum has been or needs to be resected. The J-pouch is technically easier and faster to perform [179,180]. When comparing the W-pouch with either the S-pouch [178] or

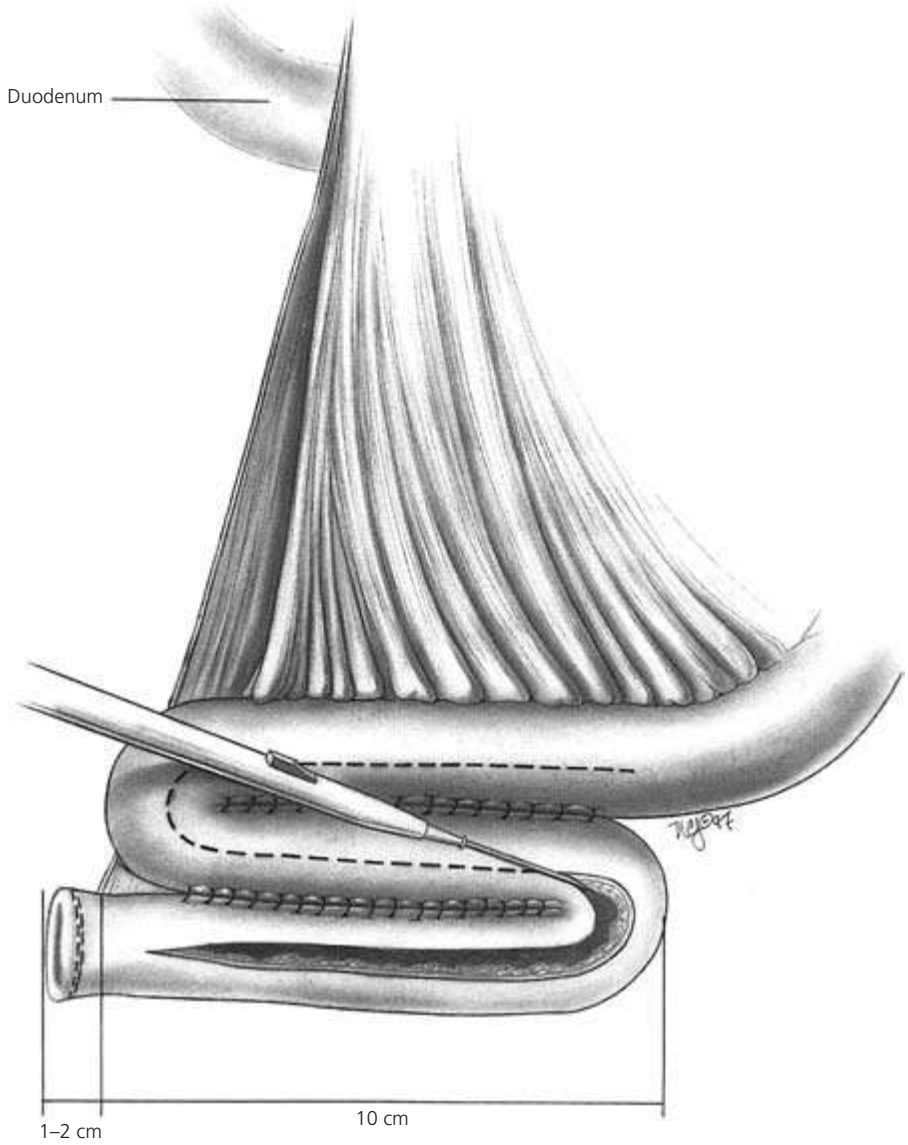

Figure 58.19 Construction of a triple loop S-pouch. From Michelassi F, Takanishi D, McLeod RS, et al. Ileal reservoirs. In: Michelassi F, Milsom JW (eds). Operative Strategies in Inflammatory Bowel Disease. New York: Springer-Verlag, 1999:186.

the J-pouch [176,181,182], patients with the W-pouch have significantly fewer bowel movements compared with the S-pouch or J-pouch group during the first 6–12 months after closure of the ileostomy. However, Keighley and colleagues [183], comparing the J-pouch with the W-pouch in a randomized prospective trial, did not confirm those findings, and Johnston and colleagues [184] showed that both types of pouches conferred the same functional results at 1 year.

We elect to perform a J-pouch for the vast majority of our patients because of the lower complication rate and the excellent functional results [135,164,179,180,185]. We reserve the S-pouch for patients in whom we suspect a difficult "reach" to the anal canal, and the W-pouch for patients in whom a substantial portion of terminal ileum has been or needs to be sacrificed.

Controversy still exists on whether the ileoanal anastomosis should be stapled or hand sewn. The initial descriptions of ileal pouch–anal anastomosis included a mucosectomy to the dentate line [141,173,186]. The anal dilation necessary for a complete mucosectomy [187] or the eversion of the anorectum advocated by some authors [188,189] caused significant decrease in the maximum resting pressure [190] and increase of the threshold sensation, which correlated with increased number of episodes of incontinence [188,189]. Furthermore, removal of the most distal lower rectal–upper canal epithelium, the anal transitional zone (ATZ), resulted in the loss of the anoderm sensory capacity, which, together with the rectoanal inhibitory reflex, allows for sampling of rectal contents and contributes to continence [191]. The technique of stapled ileal pouch–anal anastomosis was introduced to

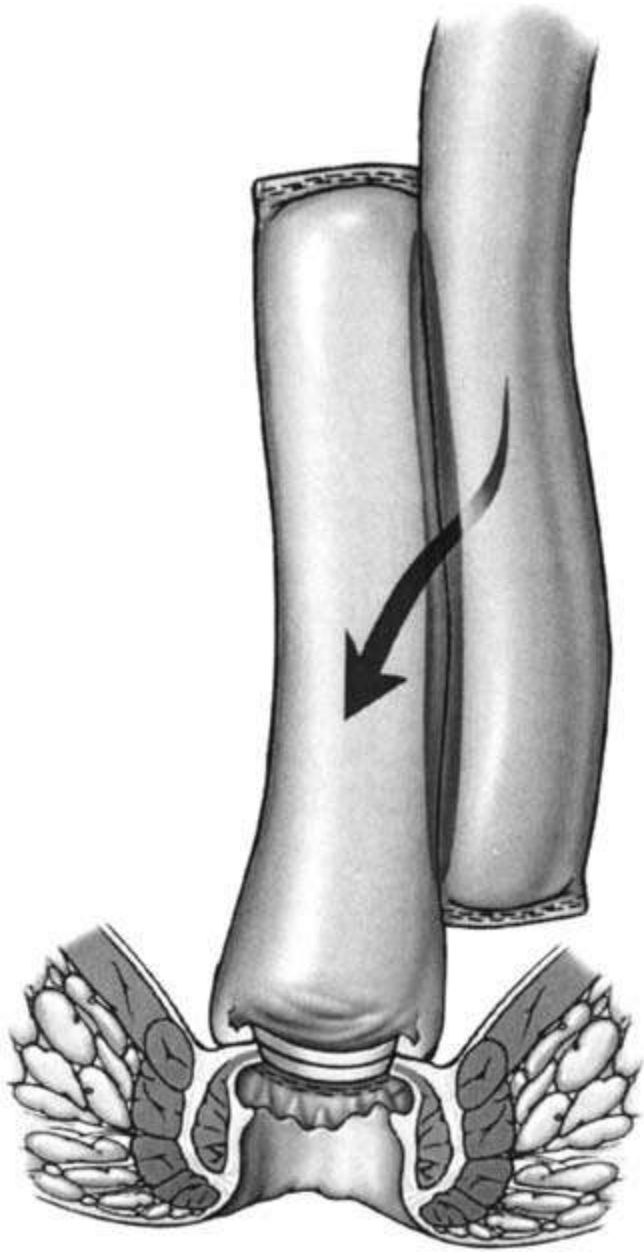

Figure 58.20 Isoperistaltic H-pouch. From Michelassi F, Takanishi D, McLeod RS, et al. Ileal reservoirs. In: Michelassi F, Milsom JW (eds). Operative Strategies in Inflammatory Bowel Disease. New York: Springer-Verlag, 1999:186.

address some of the shortcomings of the hand-sewn technique. The potential advantages of the stapled technique include less tension on the anastomosis, ease of construction, preservation of the lower rectal–upper anal canal, and less trauma to the sphincter mechanism. These advantages translate to a shorter operation with fewer anastomotic complications and, potentially, better long-term functional results.

Several comparative long-term studies have reported better functional results for the stapled ileal pouch–anal anastomosis [190,192–195]. Gemlo and associates [190] evaluated 235 patients with a mean follow-up of 70 months and found that elimination of a mucosectomy dramatically reduced nocturnal minor and major incontinence, daytime minor incontinence, and daytime protective pad use. Sagar and colleagues [195] studied anal physiological results in 20 patients up to 12 months after stapled ileal pouch–anal anastomosis. Resting anal pressure, which decreased immediately after the surgical procedure, was almost back to normal 12 months later, the rectoanal inhibitory reflex was present in 19 patients, and sampling was observed in 17 patients. The ability to discriminate flatus from feces was associated with the return of the rectoanal reflex and sampling. The functional results obtained following a stapled or hand-sewn ileal pouch–anal

anastomosis were evaluated by several prospective randomized studies [196–198]. No statistically significant differences were detected, although the validity of the results of these studies is compromised by their small size and by the short follow-up.

Several studies have looked at the rate of anastomotic complications after mucosectomy and hand-sewn ileal pouch–anal anastomosis. Preserving a short rectal cuff with the stapled technique lessens the tension on the anastomosis and reduces anastomotic complications. In a retrospective study, the Cleveland Clinic group evaluated 692 ileal pouch–anal anastomoses, 238 hand-sewn and 454 stapled. In the hand-sewn ileal pouch–anal anastomosis group, 25 patients (10.5%) had 32 septic complications, and 24 required 89 reoperations. In seven patients, the pouch was excised. In the stapled ileal pouch anal anastomosis group, 21 patients (4.6%) had 23 septic complications, and 14 required 40 reoperations. One patient needed pouch excision. Patients with hand-sewn anastomoses experienced more early septic complications and more pouch excisions related to those complications than patients with stapled ileal pouch–anal anastomosis [199]. Yet, when these complications were evaluated in prospective randomized studies, no difference was noted [196–198].

The potential disadvantages associated with preserving the ATZ include persistence of ulcerative proctitis symptoms and risk of malignant degeneration. The Cleveland Clinic [200,201] noticed that symptomatic inflammation of the retained mucosa occurred in 14.7% of their patients; 4.1% of patients had inflammation of the anal canal alone, and 10.6% had pouchitis in addition. Surgical treatment was needed in 12.9% of patients with anal canal inflammation, and in 10.6% of patients with anal canal inflammation plus pouchitis [200,201]. Such patients are usually treated with topical steroids or 5-aminosalicylate (5-ASA), and when that fails and surgical treatment is needed, a transanal mucosectomy with ileal pouch advancement is performed, with excellent results [201].

Advocates of the mucosectomy argue that the entire diseased anorectal mucosa, including the ATZ, must be removed to eliminate the risk of future dysplasia and cancer. To determine the long-term risk of dysplasia and cancer in the retained mucosal cuff after stapled ileal pouch–anal anastomosis, the Cleveland Clinic group published their series of 210 patients with at least 5 years (median 77 months) of follow-up [202]. Dysplasia developed in seven patients (3.3%) at a median of 11 months postoperatively. Patients with history of cancer or dysplasia in the colon or rectum were at a higher risk of developing dysplasia. Two patients, each with low-grade dysplasia detected on three separate occasions, underwent mucosectomy 29 and 38 months after detection of low-grade dysplasia and, fortunately, no cancer was found. The five other patients with dysplasia on one or two occasions were treated expectantly and were apparently dysplasia-free for a median of 72 months. More important, preservation of the ATZ did not lead to the development of cancer after 5–10 years of follow-up.

The actual extent of the ATZ is highly variable and mucosectomy does not ensure its complete removal. Fenger [203], using Alcian blue staining, found that the mean span of the ATZ was 8.9 mm (range 0–20 mm), starting up to 6 mm below the dentate line. By contrast, Thompson-Fawcett and colleagues [204] measured the ATZ by two techniques: whole-mount Alcian blue staining and a computer map of the histological findings based on longitudinal sections taken every 3 mm. They found that the Alcian blue technique overestimates the length of the ATZ, which usually commences just above the dentate line. The median length of the ATZ measured from computer maps of the histology was only 4.5 mm. Due to this variability, mucosectomy does not reliably remove the entire rectal mucosa [205]. Small islets of residual rectal mucosa have been identified in up to 14% of patients; in 7% at the ileoanal anastomosis [205].

This probably explains why the reported cases of cancer after a pouch procedure are all in patients who had a mucosectomy [206–208], except in one case, where the cancer was detected 16 months after stapled ileal pouch–anal anastomosis following long-standing ulcerative colitis complicated by a cancer in the upper rectum [209]. It is likely that this cancer represents a local recurrence rather than a metachronous cancer originated in the ATZ.

No hard data exist to support the superiority of one technique over the other, and there is a role for both procedures in clinical practice [135,179]. There is an advantage in preserving the ATZ in older patients with borderline sphincter function, and in tall or obese patients to decrease tension on the anastomosis. Mucosectomy may be advisable in presence of dysplasia or cancer in the colon or rectum in the pediatric population [210] and in patients with primary sclerosis cholangitis, known to have a high risk of dysplasia and cancer [211]. If the ATZ is preserved, surveillance anoscopies with biopsies are performed on an annual basis to detect dysplasia and indicate the need for a completion mucosectomy.

With the perception that anastomotic complications are reduced by the stapled ileal pouch–anal anastomosis technique, some authors have questioned the need for a diverting ileostomy [212]. The Medical College of Virginia group started to perform stapled ileal pouch–anal anastomosis without diverting ileostomy in the early 1980s [213,214]. Their series of 193 patients who underwent a stapled ileal pouch–anal anastomosis as a one-stage procedure without ileostomy, was reported with a mean follow-up of 5.1 years [214]. They noticed an anastomotic leak rate of 12% (23 patients), with 5% (9 patients) requiring a diverting ileostomy; ileal pouch–anal anastomosis function was excellent in 19 of these patients, although 2 required permanent ileostomies. Daytime stool control was 95% and nighttime control was 90%. In patients taking steroids, there was no significant difference in complication rate.

Similar results were reported by Mowschenson and colleagues [215]. Among 102 patients they reported an anastomotic leak and subsequent diverting ileostomy in 9.8%. Overall 74.8% of their patients reported total satisfaction, and 84.7% regarded themselves as being in perfect health. Once again patients on steroids did not experience a higher complication rate. These results are in contrast with several studies where patients on steroids either had a higher incidence of anastomotic complication [216–218] or were not even considered candidates for a one-stage procedure [219].

The Mayo Clinic group [160,216] and the Cleveland Clinic group [161,217] are strong advocates of a two- or three-stage operation, especially in patients who are taking more than 20 mg of prednisone. When comparing the two procedures these studies reported septic complications in up to 22% of the nondiverted group [216], and it was noted that half of the nondiverted patients with septic complications required relaparotomy for diversion and drainage, whereas none of the patients in the diverted group with septic complications required surgery of any kind [217]. A select group of patients may benefit from the avoidance of a temporary stoma and its associated complications [217]. Healthy young patients, not on immunosuppressants or steroids, whose surgery was uneventful and who show minimal tension on the anastomosis, may be better served by a one-stage procedure. Leaving a rectal tube in these patients for a few days avoids pouch distention and perianal skin irritation due to the initial diarrhea.

Proctocolectomy with continent ileostomy

The proctocolectomy with continent ileostomy, or Kock pouch, offers an alternative to an ileal pouch–anal anastomosis for a few selected patients with ulcerative colitis. Specifically, this operation should be offered in specialized centers to:

- patients with a locally advanced low rectal cancer who will need adjuvant therapy postoperatively
- patients who already have a Brooke ileostomy, after proctocolectomy, and wish to have a continent ileostomy
- patients who are not candidates for an ileal pouch–anal anastomosis because of poor sphincter function
- patients who prefer a continent ileostomy to an ileal pouch–anal anastomosis as a personal choice
- patients who have failed an ileal pouch–anal anastomosis but prefer a continence-preserving procedure to a Brooke ileostomy [220,221].

Contraindications to this procedure include older age, Crohn's disease, obesity, critical illness, and poor psychological fitness. This procedure has also been performed in the pediatric population with satisfactory results [222,223].

The distal 30 cm of the terminal ileum are used to form the internal Kock pouch. Intussuscepting the terminal ileum backward into the pouch and anchoring the intussusceptum in place with staples creates a valve that prevents distal outflow from the pouch. The end of the terminal ileum is brought to the skin surface as a flash stoma (Fig. 58.22). The patient empties the pouch intermittently by passing a catheter

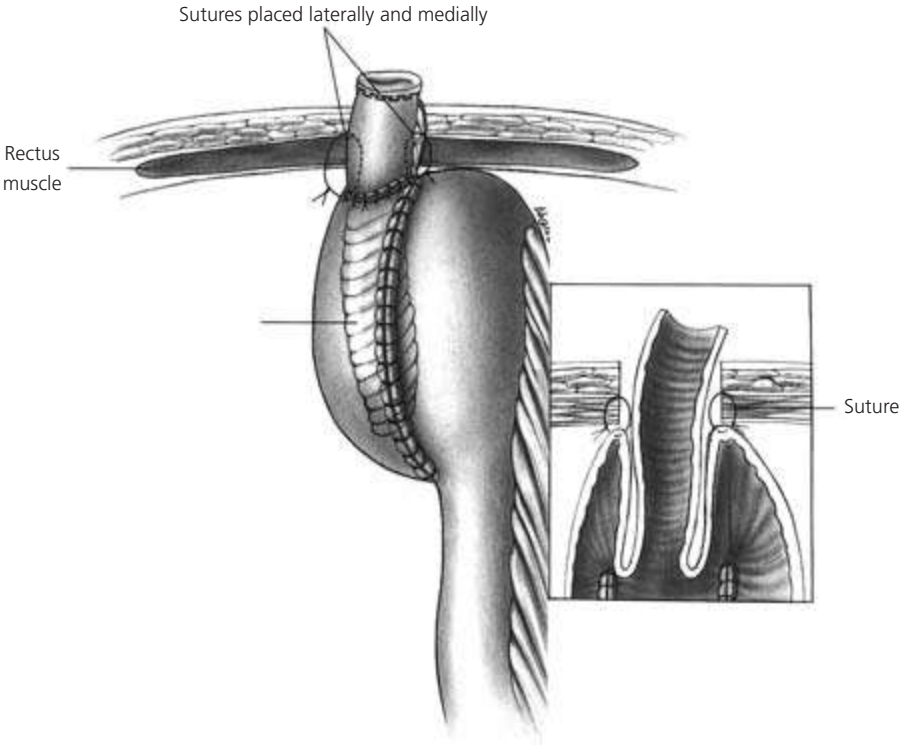

Figure 58.22 Kock pouch. From Cohen Z, McLeod RS. Proctocolectomy with Kock pouch. In: Michelassi F, Milsom JW (eds). Operative Strategies in Inflammatory Bowel Disease. New York: Springer-Verlag, 1999:215.

through the stoma and valve into the pouch. Between intubations, the pouch is continent to both gas and stool.

Kock pouch procedures have fallen out of favor because the majority of patients with ulcerative colitis undergo an ileal pouch–anal anastomosis. The largest series reporting on the Kock pouch were published in the late 1970s [220,224,225]. Overall long-term follow-up showed excellent results, between 70% and 89% continence for gas and stool, with 95% of these patients free from wearing an appliance [220,224,225]. The two main long-term problems with continent ileostomy are malfunction of the valve and pouchitis. Malfunction of the valve causes incontinence and difficult intubation of the pouch, resulting in reoperation. Between 11% and 20% of patients developed this problem [220,224,225], precipitating the need for valve revision. The incidence of pouchitis is nearly identical to that after ileal pouch–anal anastomosis, and management is similar.

Kohler and colleagues [226] evaluated quality of life in 406 patients with Brooke ileostomy, 313 with Kock pouches, and 298 with ileal pouch–anal anastomosis. They found that patients with ileal pouch–anal anastomosis had fewer restrictions in sports and sexual activity than the Koch pouch group, who in turn had fewer restrictions in these activities, but more travel restrictions than patients with Brooke ileostomy. Overall, as regards social life, recreation, work, and family activities, there was no difference between those groups and more than 90% of patients in each group were satisfied with the results [226].

Total abdominal colectomy with Brooke ileostomy

In patients who are too ill to withstand a definitive procedure for ulcerative colitis, a total abdominal colectomy with end ileostomy is warranted [227,228]. Acute toxic colitis nonresponsive to medical therapy [229] with or without megacolon or perforation or hemorrhage is the primary indication for a total abdominal colectomy–end ileostomy, and either a rectal or rectosigmoid Hartmann stump or mucous fistula. This procedure eradicates the disease, requires no bowel anastomosis or pelvic dissection, and allows the patients to be weaned off medications.

Potential candidates for a total abdominal colectomy are those patients who carry a diagnosis of indeterminate colitis. This preliminary step allows the pathologist to obtain a final diagnosis after reviewing the resected colon, thus avoiding performance of an ileal pouch–anal anastomosis in a patient with Crohn's disease. As mentioned earlier, this procedure may also be indicated in the obese patient as a first step toward an ileal pouch–anal anastomosis. In these patients, a total abdominal colectomy with Brooke ileostomy eradicates most of the active disease, allows for decrease and eventual cessation of any steroid therapy, and for the possibility of successful weight reduction.

The abdominal colectomy with ileostomy entails resection of the entire colon with exteriorization of the terminal ileum as an end ileostomy. Distally the colon is usually transected at the level of the distal sigmoid or upper rectum, based on the surgeon preference. Controversy persists regarding the management of the rectal stump. Some authors prefer to place it as a closed rectal stump into the subcutaneous tissue of the midline abdominal incision, whereas others leave it as an open mucous fistula through a separate abdominal wound [227]; the majority prefer closure of the intestinal stump and intrapelvic placement (Hartmann pouch) [227,229]. Only small comparative studies have examined this issue. Carter and associates [230] suggested that exteriorization of the closed rectal stump following total abdominal colectomy is associated with fewer pelvic septic complications and minimal local morbidity, facilitates subsequent pelvic dissection, and is not associated with increased disease activity in the retained rectum. Yet, the increased incidence of wound infections mitigates against this strategy as routine. A surgeon will be well served by choosing appropriately from the different options after having evaluated the patient's general condition, the presence or absence of generalized peritonitis, and the local status of the rectosigmoid.

The removal of the vast majority of the diseased intestine and the diversion of the fecal stream from the residual disease allow these patients to recover from the debilitating effects of high-dose medications [229], malnutrition, and sepsis. Delaying the ileal pouch–anal anastomosis does not affect postoperative functional results [228].

Colectomy with ileorectal anastomosis

Colectomy with ileorectal anastomosis is performed in only a few selected patients. The obvious advantages of this procedure are its relative simplicity, the preservation of the anal route of defecation, and the maintenance of fecal continence in all but the most debilitated patient. In addition, the risk of pelvic nerve dysfunction and perineal wound problems is virtually eliminated. Yet, this operation does not excise the diseased rectum, which maintains a risk of neoplastic transformation and may continue to cause symptoms. Indications for this conservative approach include patients with relative rectal sparing at high medical risk or older patients who are not good candidates for ileal pouch–anal anastomosis; in addition, patients with metastatic colon carcinoma in ulcerative colitis are good candidates due to their limited life expectancy [86].

Contraindications include severely diseased rectum, dysplasia or nonmetastatic rectal carcinoma, and poor sphincter function; noncompliant patients are subject to lifelong surveillance [143].

Based on the patient's medical condition and presentation, colectomy and ileorectal anastomosis may be performed as a one-stage procedure or as a two-stage procedure in those requiring emergency surgery. This operation can also be done by laparoscopic techniques.

The presence of pelvic anastomosis puts these patients at risk of septic complications due to an anastomotic leak, which occurs in about 4% of patients [84]. Dehiscences can manifest themselves in the immediate postoperative period as diffuse peritonitis, or later as abscess or fistula. When diffuse peritonitis occurs, patients need to be emergently reexplored, drained, and diverted; if the dehiscence manifests itself as a pelvic abscess, this can be treated by percutaneous, transrectal, transvaginal, transabdominal, or transperineal drainage, depending on the location of the abscess, and, possibly, proximal fecal diversion. Patients who have suffered an anastomotic dehiscence have worse functional results, with more than eight stools per day, continued need for steroids, and incontinence. Eventually, 12%–56% of these patients require proctectomy within a few years [82,231,232].

Long-term poor function can also be due to recurrent or worsening proctitis. Endoscopy and biopsy can guide in the diagnosis and treatment. Persistent disease requires either topical or systemic therapy and, ultimately, proctectomy may be necessary [144].

The risk of cancer in the rectal remnant has been reported to be 15.3% at 12 years [82], but it varies considerably between series [231,232] due to the difference in follow-up rates. The risk, however, is major, considering that most of these patients are relatively young.

More than 90% of patients with a functioning ileorectal anastomosis considered their health status to be better than before surgery [82]. Comparative studies, however, have shown no major benefit of colectomy and ileorectal anastomosis over ileal pouch–anal anastomosis in terms of postoperative morbidity, mortality, and long-term function [233,234].

Laparoscopic surgery for ulcerative colitis

As experience in laparoscopy has increased, both technique and instrumentation have improved. Laparoscopic-assisted restorative proctocolectomy has been shown by various authors to be technically safe and feasible [235–237]. In a case-matched series comparing laparoscopic and open restorative proctocolectomy procedures, Marcello and colleagues [237] have shown that return of intestinal function and length of hospital stay are reduced in the laparoscopic group without increase of morbidity or mortality. Patients undergoing laparoscopic restorative proctocolectomy have been found to have functional outcomes similar to patients undergoing open surgery and are more satisfied with the cosmetic result of the scar [238]. The laparoscopic approach has also been shown to be safe and feasible for colectomy in the setting of severe acute colitis [239].

Different techniques have been proposed for laparoscopic-assisted restorative proctocolectomy [235–237]. In general, the entire colon is mobilized intracorporeally. The mesenteric vessels are divided either intracorporeally or extracorporeally through a periumbilical or Pfannenstiel incision, based on surgeon preference and skills. The rectal dissection can be accomplished intracorporeally. Some authors, however, argue that because a Pfannenstiel incision is often used to extract the specimen, the dissection should be safely and expeditiously performed through that approach [236]. Once the specimen has been delivered through the incision, the rectum is divided at the top of the anal canal using a linear stapler, and an ileal pouch is constructed. A double-stapled anastomosis is then fashioned in a standard procedure. The use of a diverting loop has been advocated after laparoscopic-assisted ileal pouch–anal anastomosis [235–237]. The role of laparoscopy in the surgical treatment of patients with ulcerative colitis is likely to expand in the future.

Indeterminate colitis

A definitive pathological diagnosis is not feasible in 5%–20% of patients with pancolitis as the only manifestation of inflammatory bowel disease, even after the entire proctocolectomy specimen has been analyzed [66,240–243]. This group of patients has been classified as having indeterminate colitis. The fear that many of these patients with indeterminate colitis may actually harbor Crohn's disease [244] has created uneasiness about the ultimate treatment recommendation [66]. The largest series of patients with indeterminate colitis with a long-term follow-up after ileal pouch–anal anastomosis is from the Mayo Clinic [243]. The authors evaluated 82 patients with indeterminate colitis with a median follow-up of 83 months. They noticed that 15% of patients with indeterminate colitis and only 2% of patients with ulcerative colitis, as a control group, had their original diagnosis changed to Crohn's disease. At 10 years, patients with indeterminate colitis had significantly more episodes of pelvic sepsis, pouch fistula, and pouch failure (27%) than patients with ulcerative colitis [243]. Marcello and colleagues [240] also reported a 13% incidence of Crohn's disease in patients with an initial diagnosis of indeterminate colitis and a 37% pouch failure rate in this group.

Considering that approximately 15% of patients with indeterminate colitis will develop Crohn's disease over time, Bodzin and colleagues [245] advocated ileorectal anastomosis over ileal pouch–anal anastomosis in patients with indeterminate colitis. Yet, because approximately 85% of patients with indeterminate colitis will remain free of Crohn's disease, unless there are preoperative signs suggestive of Crohn's disease [93], ileal pouch–anal anastomosis, rather than ileorectal anastomosis, should be considered as an option in the treatment of these patients. Patients should be informed preoperatively that they face a higher risk of development of Crohn's disease, but should also be reassured that, after ileal pouch–anal anastomosis, they will experience long-term outcomes identical to those of patients with ulcerative colitis [243], in the absence of development of Crohn's features.

Microscopic colitis

Microscopic colitis is a cause of chronic watery diarrhea that may be accompanied by abdominal pain and weight loss. Severity can range from mild, self-limited episodes to severe, medically refractory symptoms [1]. "Microscopic colitis" was proposed in 1980 as a descriptive term for patients with chronic diarrhea and normal findings on radiographic and endoscopic examination [2]. Two subtypes of microscopic colitis are described: collagenous colitis and lymphocytic colitis. The term collagenous colitis was first used by Lindstrom in 1976 to describe a woman with chronic watery diarrhea with normal proctoscopic findings but rectal mucosal histological changes of subepithelial fibrosis and chronic inflammation [3]. In 1989, the term lymphocytic colitis was introduced by Lazenby and colleagues to describe an entity with a clinical presentation similar to collagenous colitis, yet distinguishable by the histological changes of intraepithelial lymphocytosis and expanded lamina propria without an abnormally thickened subepithelial collagen band [4]. Although both subtypes have a similar clinical presentation, they are distinguishable by these histological characteristics (Fig. 59.1a–d). The relationship between collagenous colitis and lymphocytic colitis is not clear, and it is unknown if these conditions are two separate disease entities or part of a spectrum of a single disease.

Prevalence and incidence

Microscopic colitis is found in about 10% of patients with chronic diarrhea [5,6]. Prevalence and incidence vary between collagenous and lymphocytic colitis. In North America, the prevalence of collagenous colitis is 36/100 000 population whereas the prevalence of lymphocytic colitis is 64/100 000 population [7]. The incidence of microscopic colitis in North America is increasing significantly with time (0.8/100 000 population between 1985 and 1989 compared with 19.1/100 000 population for the period 1998–2001) [7]. As with prevalence, incidence also differs between collagenous colitis and lymphocytic colitis in North America, namely 5.1/100 000 population and 9.8/100 000 population, respectively [7]. Individuals with microscopic colitis are most often in their sixth or seventh decades, and incidence increases with age. Pediatric cases and familial occurrences, although reported in the literature, are uncommon [8–13]. Historically, women reportedly have been chiefly affected, especially for collagenous colitis, with female-to-male ratios as high as 20:1 [14–17]. However, a comprehensive review of all published microscopic colitis cases through 1994 demonstrated no significant gender predominance for either collagenous colitis or lymphocytic colitis [18]. Pardi et al. found no significant gender difference in lymphocytic colitis patients [7]. An association between microscopic colitis and autoimmune disorders (e.g., celiac disease, thyroid disorders, and diabetes) and rheumatological disorders (e.g., rheumatoid arthritis) has been reported [13,15,16,18,19]. Up to one-third of patients with celiac disease may show histological changes consistent with microscopic colitis [20,21]. If patients with celiac disease do not improve on a gluten-free diet, one should consider microscopic colitis as a cause of the diarrhea [22].

Clinical features and natural history

The predominant symptom for both lymphocytic and collagenous colitis is chronic nonbloody diarrhea, with stool volumes ranging from 300 to 1700 g/24 h, with occasional fecal incontinence and decreased stool volume when fasting

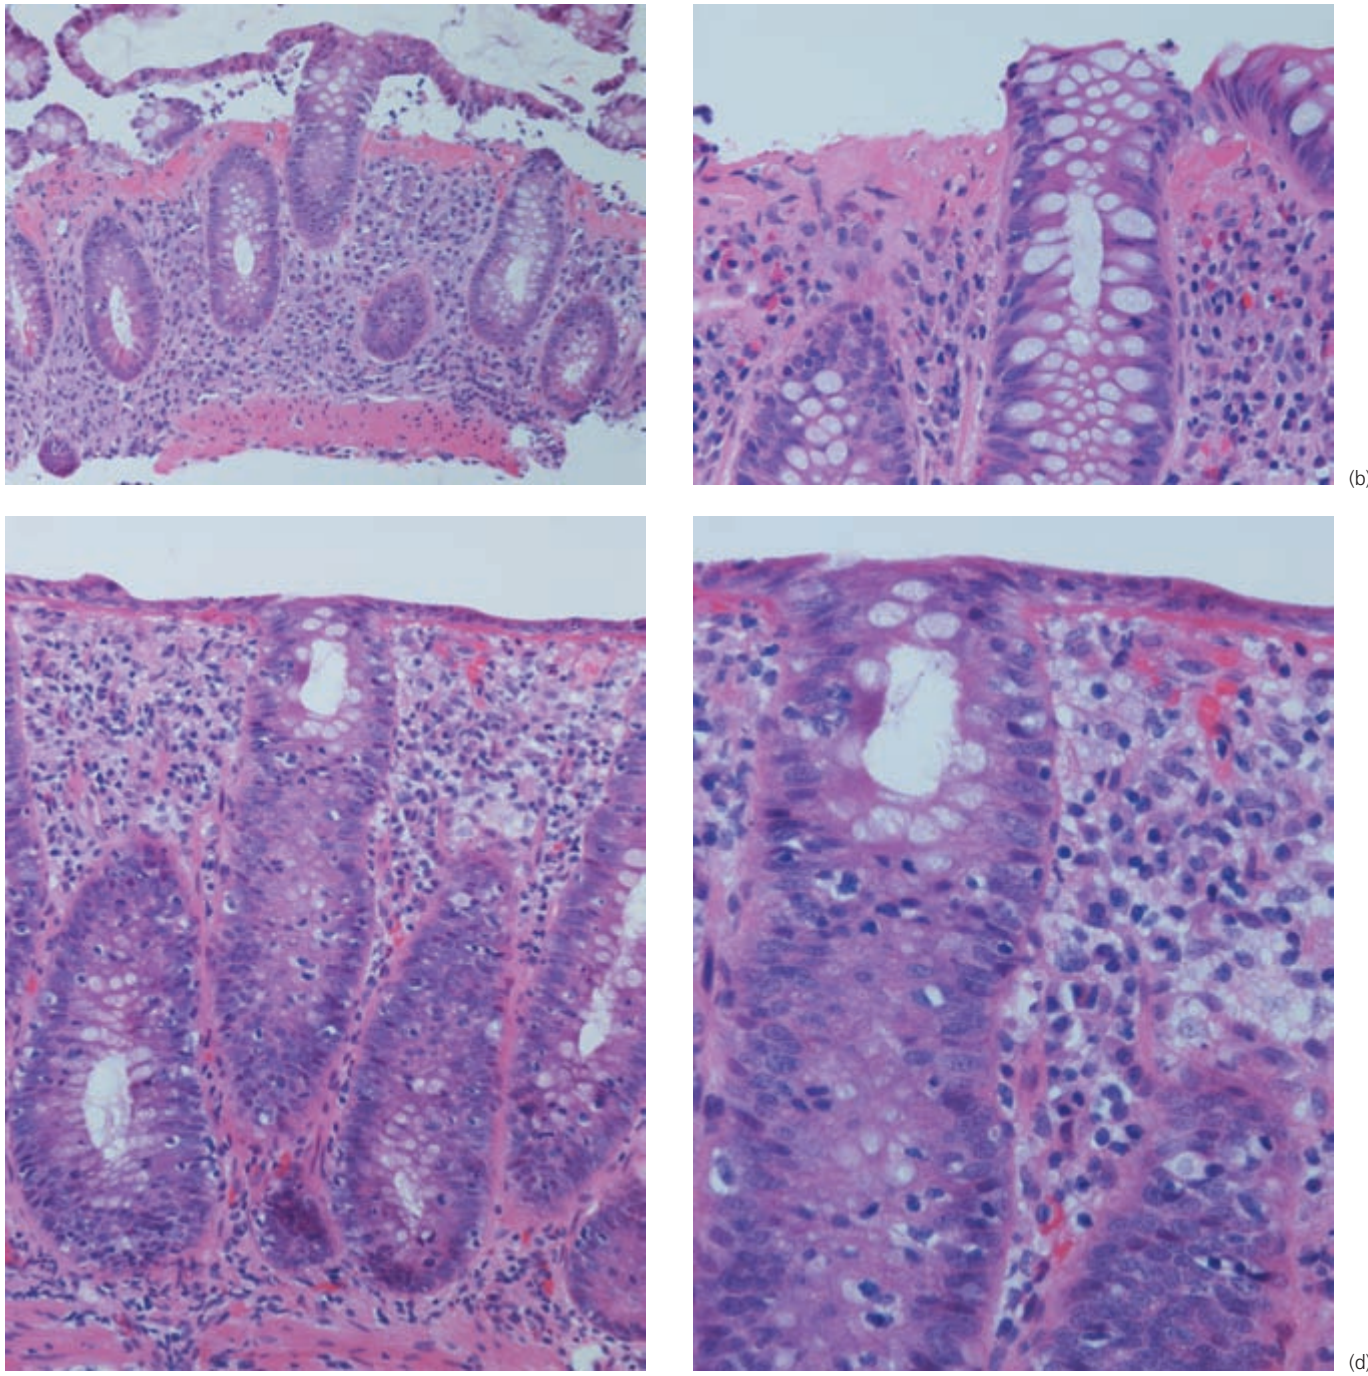

Figure 59.1 Microscopic colitis. **(a)** Lymphocytic colitis features preserved crypt architecture, lamina propria inflammation, and increased epithelial lymphocytes in surface and crypt epithelium. **(b)** The surface epithelium is often markedly flattened, as shown here. The subepithelial collagen band is not thickened. Collagenous colitis features straight crypts, slight lamina propria inflammation, and a markedly thickened subepithelial collagen band. **(c)** Stripping of the surface epithelium is characteristic. **(d)** The collagen band often contains entrapped capillaries, a helpful finding when the thickening is less dramatic than shown here.

[23]. In a study of 72 patients, in which acute onset was defined as symptoms for less than 1 week's duration, subacute as symptoms for 1–4 weeks, and chronic as persistent symptoms for which the patient could not recall a definite starting point, the onset of diarrhea in microscopic colitis was acute in 33%, subacute in 42%, and chronic in 25% [24]. There was no significant difference in the duration of the symptoms with collagenous colitis compared with lymphocytic colitis [24]. In microscopic colitis, stool frequency averages six bowel movements daily, but more than 20 bowel

movements daily is not unusual [16,25]. Other symptoms include weight loss (41%), abdominal pain (40%), urgency (29%), and nocturnal stools (22%) [26]. The presence of nocturnal stools is a feature distinguishing between microscopic colitis and irritable bowel syndrome. Fever, nausea, vomiting, and hematochezia are atypical features of microscopic colitis. Although routine laboratory tests are usually normal in microscopic colitis, electrolyte abnormalities (hypokalemia), positive serum autoimmune markers (antinuclear antibody), and elevated inflammatory markers (erythrocyte sedimentation rate) may be present. Fecal leukocytes have been noted in up to 55% of cases [27]. Malabsorption with steatorrhea or protein-losing enteropathy has been noted in rare cases [28,29].

In most cases, the colonic mucosa appears endoscopically normal, but mild edema, erythema, or a slight decrease in the usual mucosal vascular pattern have all been described [16,19,24]. Colonic ulcerations and perforation have been reported in microscopic colitis and are most likely related to the use of medications such as nonsteroidal antiinflammatory drugs (NSAIDs) [30]. Rarely, pseudomembranes may be present, giving rise to the term "pseudomembranous collagenous colitis" [31]. It is unclear if the pseudomembranes are the result of a superimposed *Clostridium difficile* infection in the setting of underlying collagenous colitis-like changes, or if the *C. difficile* infection causes both the pseudomembranes and the thickening of the subepithelial collagen band [32].

The natural history of microscopic colitis is variable. The pattern of symptoms can range from intermittent and relapsing to chronic and continuous [16]. Remission rates vary both within and between the two subtypes of microscopic colitis, and spontaneous as well as treatment-induced remission have been reported. In one study, 34% of patients with collagenous colitis and 59% of those with lymphocytic colitis remitted at 6 months [33]. Because of the high rate of spontaneous remission and the lack of long-term random maintenance studies, the optimal treatment duration remains unclear [34]. Although there have been case reports of microscopic colitis evolving into chronic ulcerative colitis and Crohn's disease and, alternatively, cases of inflammatory bowel disease (IBD) evolving into microscopic colitis, it is unclear if a true association between microscopic colitis and these other forms of IBD exists [16,35–37]. In contrast to chronic ulcerative colitis and Crohn's disease, microscopic colitis has not been identified with an increased risk of colon cancer [38,39]. In a series of 117 patients with a mean follow-up of 7 years, no cases of colorectal cancer were found and the relative risk of overall malignancy and overall mortality did not differ from the general population [38,39].

Histology

The classic histological changes in lymphocytic colitis include increased surface intraepithelial lymphocytes, preserved crypt architecture with increased crypt intraepithelial lymphocytes, and increased mixed inflammatory infiltrate, consisting of lymphocytes, eosinophils, plasma cells, and macrophages within the lamina propria [40]. Normal colon epithelium contains less than 5 intraepithelial lymphocytes per 100 epithelial cells. The intraepithelial lymphocyte count in lymphocytic colitis is 20 or more per 100 surface epithelial cells [4,33] (Fig. 59.1a,b) In collagenous colitis, the classic histological findings are essentially identical to those in lymphocytic colitis, with the exception of the presence of the thickened subepithelial collagen band, which is generally thicker than 10 µm, normal being less than 5 µm [4,41]. The thickened collagen band is most prominent beneath the surface epithelium between crypts, and frequently contains entrapped capillaries. The overlying epithelium is often detached from the collagen table. Distribution of the thickened collagen band is spotty and is most often found in the cecum (82%) and the transverse colon (83%) and least likely to be found in the rectum (72%) [42] (Fig. 59.1c,d).

There are a number of variations in the histopathological appearance of lymphocytic and collagenous colitis. Active crypt inflammation accompanied by architectural distortion and Paneth cell metaplasia [43] may be seen in otherwise typical microscopic colitis (Fig. 59.2). These findings may make it difficult to distinguish microscopic colitis from IBD. In one study, cryptitis and crypt abscesses were noted in 38% of lymphocytic colitis patients and 30% of collagenous colitis patients, whereas Paneth cell metaplasia was seen more often in collagenous colitis compared with lymphocytic colitis (44% vs 14%, respectively) [43]. Multinucleated giant cells [41], granulomas [44,45], and pseudomembranes [31] have also been described (Fig. 59.3; see also Fig. 59.2).

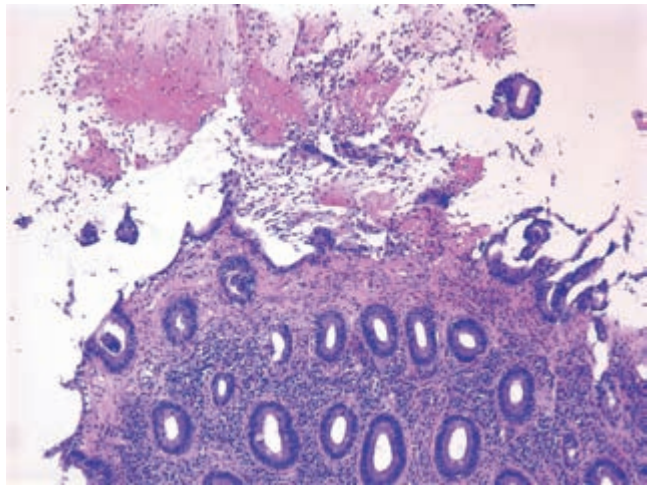

Figure 59.2 Pseudomembranous collagenous colitis. The subepithelial collagen band is thickened. The mucosal surface is covered by a mixture of fibrin and inflammatory cells in the "volcano-like" pattern typical of pseudomembranous colitis.

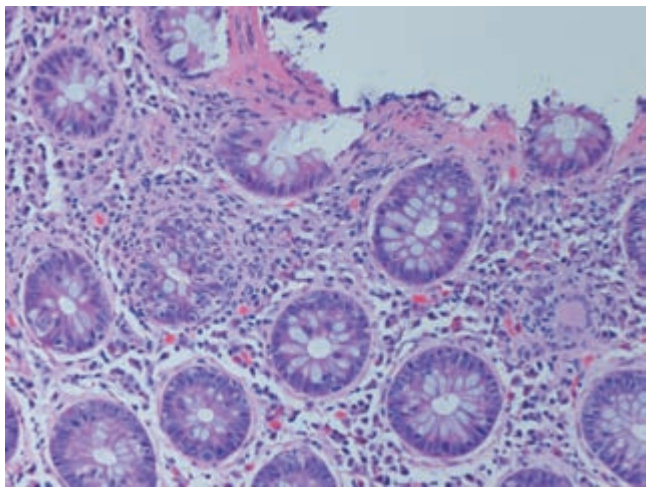

Figure 59.3 Atypical changes in collagenous colitis. There is active cryptitis on the far left and a multinucleated giant cell left of center. Neither of these changes should alter the diagnosis if the biopsy is otherwise typical of collagenous colitis.

Etiology

The etiology of microscopic colitis remains unknown. Autoimmune dysregulation, abnormal response to lumenal factor(s), drug effects, and infection have all been proposed as causes of microscopic colitis. The abnormal response to lumenal antigens hypothesis is supported by the finding that ileostomy with diversion of the fecal stream induces clinical and histological remission, and restoration of intestinal continuity results in clinical and histological relapse [46,47]. In addition, fecal extracts from patients with collagenous colitis are cytotoxic for McCoy cell cultures, and treatment with cholestyramine eliminated the cytotoxic effect [48]. Lumenal bacterial antigens may be important, and antibiotics have been therapeutic in some patients with microscopic colitis [16,49]. Given the increased infiltration and degranulation of eosinophils found in collagenous colitis, the possibility of an allergic reaction to a lumenal antigen has been proposed [50]. Indeed, dogs and cats exhibiting a disorder similar to microscopic colitis have resolution of the colonic mucosal abnormalities after being placed on a hypoallergenic diet [51]. So far, no causal antigens for the inflammatory process have been identified [52,53].

Lymphocytic colitis-like changes can be induced by administration of a gluten enema in some patients with celiac sprue [54]. Both lymphocytic and collagenous colitis can be associated with typical or refractory celiac disease. Approximately 20%–30% of patients with typical celiac disease have lymphocytic colitis on investigation by colonic biopsies [20,21,55]. Those patients diagnosed with both celiac disease and microscopic colitis are approximately 10 years younger than patients suffering only from microscopic colitis [21]. The prevalence of celiac disease in microscopic colitis patients with the reported range is from 2% to 40% [15,16,18,19,56–59]. Whether lymphocytic colitis or collagenous colitis has a stronger association with celiac disease is controversial [24,59]. Moreover, colonic inflammation not primarily caused by celiac disease responds at variable rates to a gluten-free diet, and the majority of lymphocytic colitis and collagenous colitis patients do not have malabsorption. Collagenous gastroduodenitis, collagenous enterocolitis, collagenous sprue, and autoimmune enteropathy have been reported in association with microscopic colitis [60,61].

In addition to lumenal antigens, genetic factors have been implicated in the development of microscopic colitis. Some investigators have linked celiac disease and microscopic colitis to similar HLA loci (HLA-DQ2, HLA-DQ1,3, and subtypes HLA-DQ1,7, HLA-DQ1,8, and HLA-DQ1,9), suggesting that similar immune mechanisms are involved in the development of both disease entities, but these findings have not been replicated [15,58,62]. In animal models, HLA-B27 rats developed the histological changes of collagenous colitis only in the presence of colonic bacteria [49], but this finding has not been observed in human studies. HLA-A1 was noted to be increased with diminished HLA-A3 in lymphocytic colitis, with no HLA associations noted for collagenous colitis [63], but others have not demonstrated any HLA associations [56]. Because of the inconsistent findings no definitive conclusions can be drawn regarding HLA associations in microscopic colitis.

Another hypothesis is that microscopic colitis is a stereotypical response by the gastrointestinal immune system to multiple unidentified antigens [64]. An autoimmune etiology is suggested by the findings of arthritis, thyroid abnormalities, asthma, diabetes, celiac sprue, rheumatic diseases, and hepatitis that frequently accompany microscopic colitis [16,59,65]. Concomitant autoimmune disorders are thought to be more prevalent with collagenous colitis (53%) compared with lymphocytic colitis (26%) [59]. Antiendomysial antibodies are found in 2%–4% of patients with microscopic colitis, whereas antigliadin antibodies are found in 5%–17% of microscopic colitis patients, even in the absence of celiac disease [57,58]. The antibody titers tend to be lower in microscopic colitis than in celiac disease. Perinuclear antineutrophil cytoplasmic antibodies (p-ANCA) are found in 20% of microscopic colitis patients, and the frequency of an elevated antinuclear antibody titer is mildly increased [57,66]. The roles of estrogen and progesterone have been considered as contributory or causal factors in the development of microscopic colitis, and, in one case, in the resolution of the disease with pregnancy [16].

The strong association of arthritis [44] with these disorders raises the possibility that nonsteroidal antiinflammatory drugs (NSAIDs) may play an etiological role. In some studies NSAIDs have been implicated in the development of microscopic colitis, whereas other studies have refuted this finding

[13,33,46,59,67,68]. In a well-controlled study, significantly more collagenous colitis patients (61%) had used NSAIDs for more than 6 months versus age- and gender-matched controls (13%; $P < 0.02$) [67]. By contrast, a separate case–control study found that use of NSAIDs in microscopic colitis patients (38%) did not differ significantly from age- and gender-matched controls (33%) [59]. In uncontrolled studies, 21% and 35% of patients in two collagenous colitis registries had NSAIDs [16,68]. It has been shown that NSAIDs cause gastric, small bowel, and colonic inflammation in patients and experimental animals, and can exacerbate IBD [65,68,69]. Despite these conflicting results, histological and clinical remission can occur with the discontinuation of NSAIDs, and some patients may redevelop histological changes and clinical symptoms consistent with microscopic colitis when rechallenged with NSAIDs [67,68,70–72]. Because of these findings, patients with microscopic colitis should avoid NSAIDs. Other medications, such as ticlopidine, lansoprazole, ranitidine, simvastatin, selective serotonin reuptake inhibitors, and carbamazepine, have been implicated as the cause of microscopic colitis, especially lymphocytic colitis [13,26,33,59,73–75].

In some cases of microscopic colitis, patients have a preceding acute intestinal infection, but no single pathogen has been identified. The abrupt onset of symptoms in up to 33% of patients [24] and the response in some to antibiotics [16,18,76] supports the hypothesis that an acute enteric infection is the inciting event. In addition, elevated titers of antibodies to *Yersinia enterocolitica* have been noted in patients with collagenous colitis, and the development of collagenous colitis has occurred after infection with *Y. enterocolitica* and *C. difficile* [77–80]. A chronic watery diarrhea, known as "Brainerd diarrhea," has many clinical and histological features in common with microscopic colitis. Brainerd diarrhea is associated with ingestion of raw milk, and epidemiological data indicate an infectious etiology [81]. The similarities between Brainerd diarrhea and microscopic colitis support the hypothesis for an infectious etiology for microscopic colitis.

Another theory is that the presence of lumenal bile acids leads to the colonic epithelial injury [16]. Because some patients with microscopic colitis demonstrate histological changes in the ileum as well as in the colon, this does provide a plausible explanation for why bile acid malabsorption might occur [82,83]. Investigations have noted variable frequencies of bile acid malabsorption in collagenous colitis patients as determined by an abnormal selenium-labelled homocholic acid-taurine (SeHCAT) test. Some of these patients, as well as those with a normal SeHCAT, had clinical improvement with the use of bile acid binding resins [84]. Bile acid malabsorption is only partially responsible for the development of collagenous colitis, because patients with symptomatic improvement did not always have histological improvement.

Diarrhea in microscopic colitis appears to be secretory in nature, and in a small number of patients is caused by defective active and passive absorption of sodium and chloride with reduced chloride–bicarbonate exchange [23,85–87]. Two of six patients displayed coexisting abnormal small intestinal fluid and electrolyte absorption. Active colonic chloride secretion associated with increased lumenal prostaglandin E_2 concentrations and prevention of diarrhea with a histamine H_1-receptor antagonist in a patient with increased numbers of mast cells suggest that soluble mediators produced by activated immune and mesenchymal cells mediate epithelial cell absorptive dysfunction [87–89]. This hypothesis is supported by the direct relationship between the severity of diarrhea and the numbers of mucosal inflammatory cells, and the lack of correlation with the thickness of the submucosal collagen band [90]. The latter observation argues against the hypothesis that subepithelial collagen blocks electrolyte and water absorption. Also noted in collagenous colitis are derangements in lumenal nitric oxide levels and nitric oxide synthase activity. Expression of inducible nitric oxide synthase is upregulated in the colonic mucosa of collagenous colitis patients [91], and elevated levels of nitric oxide have been noted when compared with healthy controls [92,93]. Nitric oxide acts as a secretagogue in the colon and inhibits fluid absorption by the colon. Therefore, it may play a role in the secretory diarrhea seen in microscopic colitis.

The cause of the collagen deposition in collagenous colitis is unknown. Collagen typing studies have yielded conflicting results. In some studies type I and type III collagen predominate, with an absence of type IV in the subepithelial band, but other studies have shown primarily type IV collagen deposition or a mix of collagen types [9,85,94–96]. These studies have not resolved the issue of whether the abnormal collagen band in collagenous colitis is normal collagen that is overproduced as part of the repair process, or if it is an abnormal collagen. Type III collagen is typically found when tissues are repairing after an injury, whereas type IV collagen indicates a primary abnormality of collagen production [97]. Myofibroblasts within the pericryptal fibroblast sheath, which surrounds and gives support to the crypt epithelium, may become sequestered within the collagen band and be responsible for the increased collagen production deposition [46,98]. Transforming growth factor-β (TGF-β) is overexpressed in patients with collagenous colitis, which may lead to collagen accumulation in tissues, and there is evidence to suggest that the rate of collagen degradation is decreased [95,96]. It remains unknown why this abnormality in the sheath is not present in lymphocytic colitis. This gives reason to consider that the collagen deposition is not the primary defect, but occurs in response to the inflammatory infiltrate. This hypothesis is supported by the fact that the diarrhea in collagenous colitis does not seem to be related to the thickness of the collagen band but rather the degree of inflammatory infiltrate, as noted above [90].

Diagnosis

A minority of patients (24%–29%) with microscopic colitis, collagenous colitis in particular, have nonspecific endoscopic abnormalities including erythema, edema, or abnormal vasculature [16,24]. In a study of 362 patients who underwent colonoscopy for evaluation of diarrhea, significant histopathology was noted in 18 (5%), with a significantly higher prevalence of microscopic colitis in patients over 60 years of age (7% vs 0.4%) [99]. Multiple biopsies must be taken from different colonic segments to diagnose microscopic colitis [27,42,100]. Colonoscopy with biopsy of multiple segments demonstrated only one site positive in 5 of 17 patients, and a greater than 50% variability of the collagen band thickness in multiple samples taken simultaneously [42]. Flexible sigmoidoscopy is an adequate screening exam, with approximately 95% of pooled biopsies from the descending colon, sigmoid colon, and rectum showing changes of chronic inflammation or a thickened collagen plate [27,42]. However, if suspicion remains high for microscopic colitis despite negative left colon biopsies, one should consider a colonoscopy with proximal colon and random biopsies. Ileoscopy should be undertaken, if possible, as it may identify up to 5% more abnormalities than colonoscopy to the cecum [99]. Biopsies of a normal-appearing ileum have a low yield and typically are not useful. Proper orientation of the histological specimen is essential to prevent artifactual thickening of the subepithelial basement membrane caused by tangential sectioning. The presence of associated lamina propria inflammation is an important co-diagnostic feature of collagenous colitis [4].

Stool weight in microscopic colitis is usually 500–750 g/day, with an electrolyte pattern consistent with secretory diarrhea [101]. Crohn's disease and chronic ulcerative colitis can be differentiated from microscopic colitis by diagnostic radiography and colonoscopy as well as by histology. This can become more difficult in those microscopic colitis patients who exhibit "atypical" morphological features, often associated with chronic ulcerative colitis and Crohn's disease [43]. Crypt abscesses, crypt architectural abnormalities, the presence of neutrophils, lymphocytes within the crypts, giant cells, and the presence of granulomas have been reported in microscopic colitis [40]. Pericrypt eosinophilic enterocolitis is characterized by chronic watery diarrhea and normal endoscopy, but may be differentiated from lymphocytic colitis by the absence of increased numbers of intraepithelial and superficial lamina propria lymphocytes and the presence of eosinophilic infiltration, crypt foreshortening, and inflammation in the deep lamina propria and muscularis mucosa [102]. Infectious agents may be excluded by stool examination for ova and parasites, standard bacterial stool cultures, and *C. difficile* toxin assays. Jejunal aspirates can be performed to rule out bacterial overgrowth and *Giardia* infection. Given the increased occurrence of celiac disease in microscopic colitis patients, small bowel biopsies can be performed to rule out both celiac disease and Whipple disease. Irritable bowel syndrome can typically be differentiated by normal stool volume and normal or nearly normal colonic biopsies. Malabsorption, although uncommon in microscopic colitis, may be present. Hormone-producing tumors, hyperthyroidism, and laxative abuse could be considered if the history or physical examination are suggestive. Ischemic colitis should be considered if clinically relevant. Histologically, the fibrosis that occurs with ischemic colitis, radiation injury to the bowel, and solitary rectal ulcer syndrome (SRUS) is diffuse within the lamina propria. The collagen deposition that accompanies progressive systemic sclerosis occurs along the basement membrane and may be transmural throughout the colonic wall. Amyloidosis can be a cause of chronic watery diarrhea, and amyloid deposition occurs along the basement membrane of the crypts, blood vessels, and surface epithelium. Histochemical staining can be used to diagnose amyloidosis.

Treatment

There are few prospective controlled trials for the treatment of microscopic colitis. Clinical symptoms of microscopic colitis tend to wax and wane in a relapsing remitting fashion. Many cases spontaneously improve. This makes it difficult to interpret the results of the small, mostly retrospective, therapeutic studies. Most agree that initial therapy should focus on the discontinuation of agents and substances that are potential causes of diarrhea, such as dairy products, excess alcohol intake, and excessive caffeine intake [32]. If possible, NSAIDs and other potential causative medications should be stopped. Antidiarrheal therapies are well-tolerated and can be effective [16,76]. Bismuth subsalicylate has been noted to be helpful in some patients with microscopic colitis. Bismuth possesses antiinflammatory, antidiarrheal, and antimicrobial properties. Fine and Lee reported that 11 out of 13 patients with microscopic colitis responded to oral bismuth subsalicylate, eight tablets (262 mg each) per day for 8 weeks; there was a durable remission with complete resolution of histological changes in 9 subjects [103]. Pardi et al. noted that bismuth subsalicylate at a dose of eight tablets (262 mg each) per day taken in 3–4 divided doses led to a complete response in 23% of patients and a partial response in 50%, with only 4% of patients intolerant to the medication [76]. In one small randomized controlled trial of bismuth subsalicylate, a regimen of three 262-mg tablets, administered orally three times a day for 8 weeks, was tested versus placebo. Of the nine patients, four showed clinical and histological improvement with bismuth subsalicylate, whereas the remaining five assigned to placebo did not improve ($P = 0.003$) [104]. Improved symptoms and histology have been noted following the use of 5-aminosalicylate (5-ASA) products and sulfasalazine. Whereas one review noted improvement in the majority of patients using 5-ASA products, other studies have noted less promising remission rates [13,16,18,76]. In one large retrospective review, 15% of patients reported a complete remission of diarrhea and another 27% reported

a partial improvement in diarrhea [76]. In general, response rates of 40%–50% are seen with mesalamine (rINN mesalazine) and sulfasalazine. Bile acid-binding drugs have been used with some success, both clinically and for mucosal healing, in patients with microscopic colitis [105]. This is particularly true in those patients who demonstrated evidence of bile acid malabsorption by the SeHCAT retention test [105]. Traditional corticosteroids, such as prednisone and prednisolone, have been used for microscopic colitis. In a retrospective study, 82% of collagenous colitis patients treated with prednisolone had a clinical response, whereas 59% and 50% responded to sulfasalazine and mesalamine, respectively [16]. In addition, response to metronidazole or erythromycin was 55% and 67%, respectively [16]. Although corticosteroids have been shown to be effective in uncontrolled series, only one randomized controlled trial of prednisolone has been completed [16,19,76,106]. Prednisolone 50 mg per day for 2 weeks was compared with placebo in the treatment of 12 patients, 11 of whom had collagenous colitis [106]. Complete remission was noted in only two patients. This was not significantly different from placebo although prednisolone decreased the mean stool weight and reduced the frequency of bowel movements from six per day to three per day in the treatment group [106]. A longer course of therapy may be necessary to see improvement both clinically and histologically. In a separate controlled trial, six patients with collagenous colitis (43%) had a significantly decreased number of stools ($P = 0.03$) and a decrease in the degree of mucosal inflammation (not quantitated) after 3 months of prednisolone therapy. Stool frequency returned to pretherapy levels within 2–4 weeks after cessation of therapy; however, the thickness of the collagen band was unchanged by treatment in five of six patients [107]. Patients treated with steroids tend to relapse on withdrawal of the steroid medication, and many are left steroid dependent [16,19]. Because the side effects of traditional corticosteroids can lead to short-term and long-term health concerns, budesonide has been utilized. Budesonide is a synthetic corticosteroid with low systemic bioavailability as a result of its metabolic characteristics, and is one of the most extensively studied drugs in the treatment of microscopic colitis. Budesonide primarily acts locally in the distal ileum and right colon with some minor absorption in the transverse and descending colon. Due to the high first-pass metabolism, the side-effect profile of budesonide is preferable to that of traditional corticosteroids [108–110]. In a Cochrane review of three randomized controlled trials of budesonide versus placebo in the treatment of collagenous colitis, the pooled odds ratio for response to therapy was 12.32 [95% confidence interval (CI): 5.53–27.46]. The number needed to treat (NNT) was 2 patients. It should be noted that treatment regimens differed between the three budesonide studies. The dose varied from 9 mg/day for 8 weeks [111], 9 mg/day for 6 weeks [112], and 9 mg of budesonide for 4 weeks with a 3-mg taper every 2 weeks for a total duration of therapy of 8 weeks [113]. Interestingly, all studies showed a benefit in clinical symptoms over that seen by placebo, with response rates ranging from 57% to 100% [111–113]. The time to clinical response was between 12 and 14 days [111,112,114]. The rates of histological remission were significantly superior to placebo in all three randomized controlled trials of budesonide, with rates ranging from 54% to 100% [111–114].

Immunomodulators have shown efficacy in the treatment of microscopic colitis patients who are intolerant of, refractory, or dependent on steroid therapy. Among nine steroid-dependent or steroid-intolerant microscopic colitis patients treated with a median azathioprine dosage of 2 mg/kg/day, five (56%) experienced resolution of symptoms and were successfully tapered off steroids, three (33%) were able to taper or discontinue steroids but were left with mild diarrhea, and one patient required an ileostomy for persistent severe diarrhea [115]. These patients maintained remission or improvement in diarrhea for a median follow-up of 26 months. However, adverse events such as infection, nausea, mild leukopenia, and liver abnormalities required four patients to be successfully switched to 6-mercaptopurine (6-MP). As the prognosis of microscopic colitis is good and the rate of adverse events small, with no risk of increased mortality, use of these medications should be reserved for those patients who face severely debilitating symptoms or severe side effects from their current therapy [115].

Uncontrolled studies have reported symptomatic benefit with antibiotics, methotrexate, cyclosporine (ciclosporin), octreotide, and calcium channel blockers [16,19,76,116,117]. In the rare situation when all medical options have failed, surgery is a consideration. Ileostomy without colectomy, ileostomy with colectomy, and ileal pouch–anal anastomosis have been shown to be effective in controlling diarrhea [46,76,115,118].

The following progressive evidence-based approach is recommended for treatment of microscopic colitis [32]. Initial therapy should focus on withdrawal of agents possibly responsible for diarrhea and implicated in the development of microscopic colitis. Symptomatic control should be attempted with antidiarrheal therapy, such as loperamide or diphenoxylate hydrochloride/atropine. If symptoms continue and are mild, bismuth subsalicylate, eight or nine 262-mg tablets, taken in three or four divided doses daily, can be added. In the event that no improvement or remission occurs, the use of cholestyramine or 5-ASA products should be considered. For more severe symptoms and in patients with mild symptoms who have failed symptomatic measures, budesonide, 9 mg per day for 6–8 weeks, is appropriate. In patients who are refractory to other medical interventions, azathioprine and 6-MP are options. In refractory patients with severe symptoms, other options are octreotide, methotrexate, and cyclosporine, or surgical intervention. When a medication leads to clinical remission or improvement,

it should be continued for 6–8 weeks and then stopped, given that spontaneous remissions occur and treatment can lead to a durable remission. If symptoms recur on discontinuation of the treatment, the initial treatment should restarted, as patients have been shown to respond favorably when rechallenged with the same initial medical therapy [103,104,119,120].

Distinct entities or not?

There is controversy as to whether lymphocytic colitis and collagenous colitis are two distinct entities or represent a continuum of the same disorder or different phenotypic manifestations of the same disorder. Both lymphocytic and microscopic colitis share similar clinical, demographic, and histological characteristics and differ primarily according to the the presence or absence of a thickened subepithelial collagen band. The etiology of the collagen band remains unknown. Serial biopsies have shown both resolution and appearance of the collagen band with time [15]. However, other investigators have demonstrated that the collagen band has a patchy distribution and this calls into question the theory that lymphocytic colitis and collagenous colitis are distinct clinical entities. Further investigations into the cause of microscopic colitis are necessary before this debate can be put to rest.

Drug- and chemical-induced colonic injury

Colonic injury and inflammation has been attributed to a number of orally and rectally administered substances. These agents may cause colonic injury through a number of mechanisms, including direct mucosal injury and ischemic injury. This section will review the most common types of drug- and chemical-induced injury, with an emphasis on pathogenesis and clinical findings.

Syndromes associated with enema use

Various rectally administered substances are common causes of toxic colitis. Traditional soapsuds enemas, radiographic contrast media, hydrogen peroxide, herbal enemas, and residual disinfecting agents on the colonoscope have been shown to be associated with toxic colitis. Mechanisms of injury include direct mucosal toxicity from corrosive acids, bases, and caustic agents; intracellular explosive oxygen production (hydrogen peroxide); osmotic shifts due to hypertonicity of the enema solution (radiographic contrast agents); and cross-linking of extracellular and intracellular proteins (formalin) [121]. Risk factors include radiographic contrast media enemas, detergent enemas, and a history of self-mutilation. The severity of the colonic injury depends on the type of substance, the concentration of the substance, and the duration and extent of mucosal contact. Affected individuals typically present with abdominal distention, pain, bloody or nonbloody diarrhea, tenesmus, and possibly fever. Physical examination may reveal abdominal tenderness, possibly with peritoneal signs, and rectal tenderness. Laboratory investigation may demonstrate leukocytosis and elevated serum inflammatory markers [122]. On physical examination there may be perianal excoriation. Endoscopy may reveal friable mucosa with or without ulceration or pseudomembranes, or segmental distal colitis. Treatment is supportive with bowel rest, intravenous fluid administration, and, if clinically indicated, broad-spectrum antibiotics. Surgery may be necessary in more severe cases with necrosis and perforation [122].

Water-soluble contrast media

Hyperosmolar water-soluble contrast media, such as Gastrografin (Bracco Diagnostics Inc., Princeton, NJ), Hypaque (Nycomed Inc., Princeton, NJ), and Renografin (Bracco Diagnostics Inc., Princeton, NJ), are often used to relieve fecal impactions and to opacify partial colon obstructions, avoiding the potential complications of barium enema. Although these agents are generally safe, a mild to severe colitis can result from their use [123]. Because these contrast agents are hypertonic, they facilitate passage of stool by drawing liquid into the lumen of the colon. The addition of the detergent Tween 80 may also aid in passage of stool. Yet, the same properties that help to facilitate stool passage, namely the hypertonicity of the contrast media and the presence of an agent with detergent properties, are thought to contribute to the mucosal damage in the colon. It may be that lumenal distention leads to decreased blood flow to the colonic mucosa [124]. In most reports, contrast media-induced colitis has occurred proximal to an obstruction, chiefly in the cecum and ascending colon [121].

Sodium phosphate solutions

Their advantages of cost-effectiveness and the need to ingest smaller volumes mean that sodium phosphate preparations are being used more commonly for colonoscopy. In an outpatient setting in Canada, one group noted that sodium phosphate was used more often than the traditional polyethylene glycol (PEG) preparation in the outpatient setting (46% vs 35%, respectively; $P < 0.02$) [125]. However, sodium phosphate bowel preparations are not suitable for use in some patient groups, namely those with renal failure, heart disease, and those individuals prone to electrolyte disturbances, because this type of preparation has been reported to cause hyperphosphatemia, hypokalemia, and hypocalcemia [126]. Indeed, there is one case report of acute renal failure induced by use of sodium phosphate bowel preparation in a previously healthy patient with no history of renal failure [127]. In addition, sodium phosphate preparations have been shown to lead to more episodes of dehydration when compared

with PEG preparations (9% vs 3%, respectively; $P < 0.02$) [125]. Variable rates of colonic mucosal injury have been reported with the use of sodium phosphate bowel preparations. Zwas et al. randomized 97 patients to sodium phosphate or PEG prior to colonoscopy, and noted the occurrence of aphthoid lesions of the colonic mucosa in 25% and focal active colitis in 6% of patients receiving sodium phosphate as compared with 2% of patients who received PEG [128]. However, in a study of 687 consecutive patients receiving sodium phosphate as colonic preparation, a 6.1% incidence of any type of colonic mucosal abnormality was noted, which included both endoscopically apparent lesions, such as aphthoid ulcerations, which were noted in 2.6% of patients, and microscopically apparent lesions, such as focal active colitis and aphthoid lesions, which were noted in 3.5% of patients [129]. Lesions are usually found in the left colon but can occur at any location. Endoscopically, the mucosa may appear edematous and erythematous, with the appearance of aphthoid lesions ranging from petechial markings on the mucosa to discrete superficial ulcerations surrounded by a circumferential halo of edema and normal adjacent colonic mucosa [130]. Histologically, sodium phosphate-induced colonic injury demonstrates focal neutrophilic cryptitis and the presence of apoptotic bodies within the crypts (Fig. 59.4a–c). The surrounding mucosa may or may not demonstrate neutrophils in the lamina propria [129].

The mechanism of injury induced by sodium phosphate bowel preparation is unknown. It has been hypothesized that direct mucosal injury, apoptosis of crypt cells, increased epithelial proliferation, and oxidative damage may play a role in colonic injury [129,131]. Biopsies of sodium phosphate-induced mucosal lesions demonstrate an increased number of apoptotic bodies when compared with biopsies of normal mucosa in a non-sodium phosphate-treated bowel [129].

Diagnosis is made by endoscopic and histological appearance in conjunction with the clinical history of the patient. It is important to distinguish these lesions and ulcerations from those of IBD, namely Crohn's disease.

Treatment is simply supportive, and the lesions resolve on cessation of exposure to the offending agent.

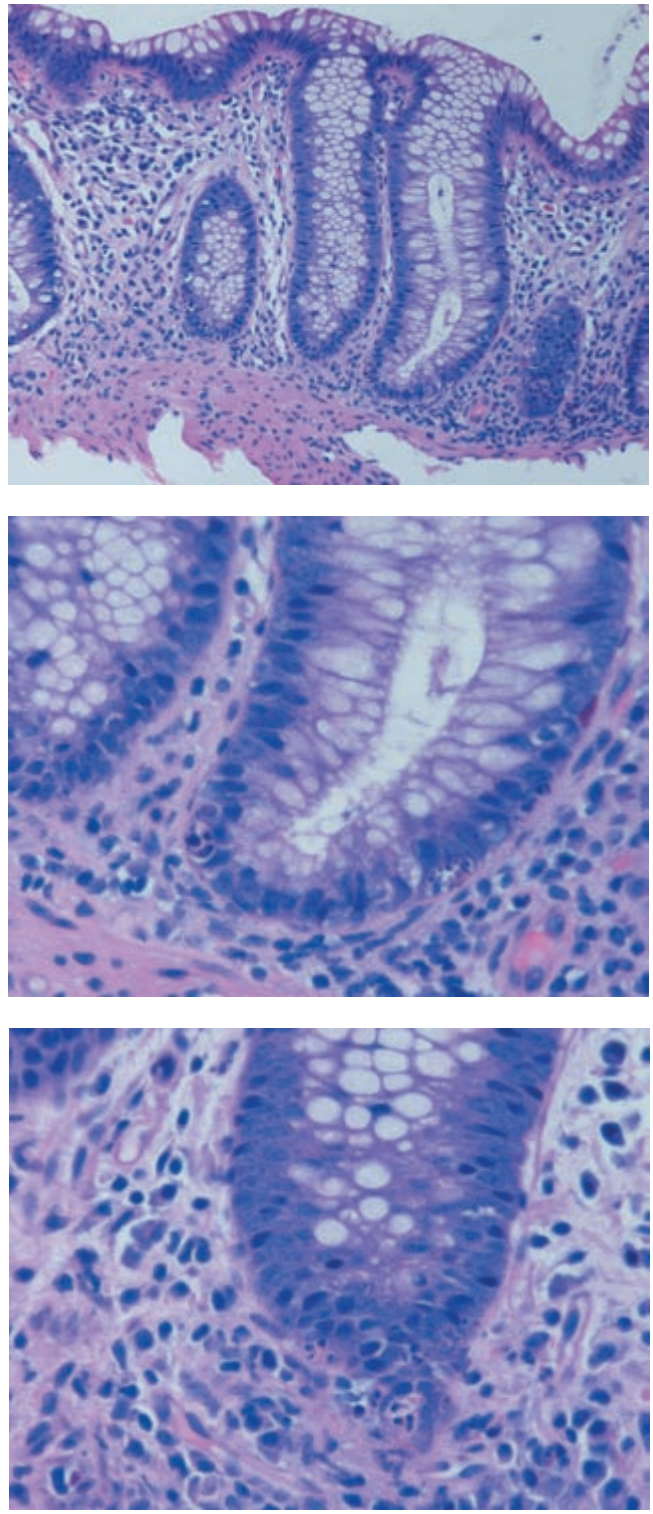
Other miscellaneous substances

Many other substances, when introduced into the rectum, can result in extensive tissue damage to the colonic mucosa. Enemas consisting of vinegar [132], ethanol [133], hydrofluoric acid, potassium permanganate [132], and chloroxylenol (Dettol) [132] are just a few of the agents that can result in variable degrees of colonic inflammation and necrosis.

Syndromes associated with laxative abuse

Melanosis coli

First described in 1835 by Billiard and named by Virchow in 1857, melanosis coli is characterized by a brown to black



(a) (b) (c)

Figure 59.4 Mucosal changes produced by sodium phosphate bowel preparation solution. **(a)** The crypts are straight, the lamina propria is not inflamed, and the surface epithelium is normal. **(b)** There is apoptotic debris at the crypt base. **(c)** Occasionally, neutrophils accompany the apoptosis. The latter can be mistaken for Crohn's disease.

pigmentation of the colonic mucosa that is associated with chronic laxative use. It is typically found in patients who chronically use anthranoid laxatives, such as sennosides, cascara frangula, rhubarb, and aloe, but may be seen in patients who do not use laxatives and suffer from constipation [134]. Up to 73% of patients using anthranoid laxatives develop melanosis coli [135], and a study noted a three-fold increased risk of melanosis coli with anthranoid laxative use [136]. Changes of melanosis coli can occur as early as 4 months after beginning ingestion, and generally regress within 9–12 months of stopping the anthranoid laxative [137]. Patients with endoscopic or histological findings of melanosis coli are not always laxative users. Pardi and colleagues noted melanosis coli in 25 patients with underlying IBD; however, only 20% admitted to use of laxatives [134]. This retrospective investigation highlights the fact that not all cases of melanosis coli are associated with the use of laxatives, and also raises the possibility that IBD is a risk factor for development of melanosis.

Because the pigmented changes initially were thought to be due to deposition of melanin or a melanin-like pigment, the disorder was named "melanosis coli." However, studies have revealed that the pigmentation is due to lipofuscin and partially digested cell organelles originating from apoptotic enterocytes [138]; therefore, this disorder is more correctly known as "pseudomelanosis coli." The pathogenesis of pigmentation is thought to involve anthranoid-induced apoptosis of colonic epithelial cells, which leads to phagocytosis and degradation of these apoptotic bodies by macrophages, leading to the formation of pigment-laden macrophages. These macrophages then migrate deep into the lamina propria and into lymph nodes [138]. This hypothesis is supported by the finding of significantly increased apoptotic bodies in those patients treated with an anthranoid laxative 6 h prior to colonoscopy and in those with severe melanosis coli when compared with controls ($P = 0.001$ and $P = 0.02$, respectively) [139].

Endoscopic evaluation may demonstrate findings of a brown to black pigmented colon, which can involve the entire length of the large intestine. Colonic adenomas and adenocarcinomas lack pigmentation and may appear as islands of unpigmented mucosa in a background of a darkly pigmented colon. This is thought to occur because the apoptotic bodies of adenomatous or neoplastic tissue tend to stay within the epithelial layer instead of migrating to the lamina propria, the location where macrophages typically ingest and degrade these bodies into lipofuscin-like pigment [138]. Therefore, these nonpigmented areas should be biopsied. Histologically, the macrophages within the lamina propria are increased in number and size, and are situated between the crypts. These macrophages are filled with a brown granular pigment, and it has been noted that the most pigment is found in those macrophages farthest from the lumen. This is thought to be the result of increased degradation of intracellular material as the macrophage migrates downward toward the lymph vessels [138]. The colonic epithelium appears normal under light microscopy, but electron microscopy demonstrates decreased numbers of microvilli, vacuolization of the apical cell surface, and small vesicles near the lateral cell membrane [140].

Many regard anthranoid laxatives as harmless, "herbal" laxatives, but reports have linked melanosis coli to an increased incidence of colonic adenomas [141] and colonic adenocarcinomas [142]. However, a case–control study found no association between the occurrence of preneoplastic lesions of the colonic mucosa, known as aberrant crypt foci, and the presence of melanosis coli or laxative use [136]. Overall, melanosis coli is generally regarded as a benign condition that remits with cessation of the laxatives.

Cathartic colon

Heilbrun in 1943 described the first case of cathartic colon when he described markedly abnormal radiographic studies in a young female with a 20-year history of laxative use [143]. Cathartic colon is an uncommon disorder that occurs in individuals, frequently middle-aged women (mean age 55), who have abused irritant laxatives for an average of over 26 years [144]. Interestingly, cathartic colon appears to have dramatically decreased in recent years.

Drugs resulting in ischemic colonic injury

Ischemic injury of the colon results from compromised mucosal blood flow, which can occur for a number of reasons. Most commonly, it is a disorder of the elderly population, brought about by atherosclerotic disease, arrhythmias, hypotension, hypercoagulopathy, and valvular heart disease. The occurrence of this condition in younger patients should prompt a thorough investigation into risk factors, including medication usage. Ischemia of the bowel typically occurs in watershed areas, such as the splenic flexure of the colon. Medications can induce ischemic colitis by a number of mechanisms: vasospasm, thrombosis, decreased blood delivery to the mesenteric vessel, extrinsic compression of the vessels as a result of fibrosis, and idiopathic mechanisms [121]. Patients with ischemic colitis present similarly, although the severity of the symptoms depends on the severity of the ischemia and which mesenteric vessel is involved. Abrupt onset of severe abdominal pain, tenesmus, bloody or nonbloody diarrhea, nausea, and fever are all possible presenting symptoms. Hypoactive to absent bowel sounds and rebound or guarding may be present, although classically the clinical symptoms are out of proportion to the physical examination findings. Leukocytosis is not always present. Abdominal plain films may show dilated bowel, "thumbprinting," pneumatosis coli, or pneumoperitoneum. Endoscopic investigation may reveal variable degrees of mucosal edema, erythema, friability, granularity, ulceration with or without pseudomembranes, and pale or dusky mucosa.

Ergotamine

Ergotamine is a medication indicated for the treatment of migraine headaches. The use of ergotamine can lead to vasospasm-induced ischemic colitis. The first case reported involved a 50-year-old woman using ergotamine tartrate who developed acute colitis of the splenic flexure, which resolved after discontinuation of the medication [145]. In addition, patients may develop proctitis after use of ergotamine suppositories [121,145,146]. Endoscopy may demonstrate shallow geographical rectal ulcers that resolve on withdrawal of the medication [121]. Histologically, obliteration of the small blood vessels with vascular wall thickening is noted [147]. Other migraine therapies, such as sumatriptan, have also been reported to cause ischemic colitis [148].

Oral contraceptives

The association between ischemic colitis and hormones such as estrogen and progesterone has been known for decades. Both estrogen and progesterone, in their various forms, can lead to a hypercoagulable state, vasospasm in the mesenteric vessels, and endothelial proliferation with subendothelial fibrosis, all of which may play a role in oral contraceptive-induced ischemic colitis [122,149]. The dose of the estrogenic factor correlates with the degree of thrombogenicity [122]. Both venous and arterial mesenteric thrombosis have been associated with the use of oral contraceptives. Mesenteric arterial thrombosis occurs less often but carries twice the mortality of venous thrombosis. In a single-institution review of 39 adults aged under 50 years and diagnosed with ischemic colitis over a period of 9 years, a strong female predominance was noted and 52% of the women were taking oral contraceptives at the time of diagnosis [150]. The rectosigmoid and the splenic flexure are the most commonly affected sites. Withdrawal of the oral contraceptive is indicated if ischemic colitis develops while on therapy.

Cocaine

Cocaine leads to intense vasoconstriction as a result of catecholamine release and has been linked to the occurrence of severe ischemic colitis. Intestinal ischemia can develop after intranasal, intravenous, or oral administration of cocaine [151]. A review noted that the majority of cases affect the proximal colon [152]. Many patients require resection of gangrenous bowel.

5-HT$_3$ receptor antagonists

Alosetron is a selective serotonin (5-hydroxytryptophan, or 5-HT) antagonist that targets 5-HT$_3$ receptors. It is indicated for the treatment of females with severe refractory diarrhea-predominant irritable bowel syndrome (IBS). In post-market monitoring of adverse reactions, a number of patients developed ischemic colitis, and these cases were reported to the US Food and Drug Administration, which resulted in the subsequent withdrawal of the drug from the US market [153]. Also, eight cases (six women and two men) of ischemic colitis have been reported with another 5-HT$_3$ antagonist known as cilansetron [154]. Therefore, it appears that ischemic colitis may be a side effect common to all drugs of this class. A number of hypotheses exist regarding the mechanism by which alosetron leads to ischemic colitis: vasoconstriction as a result of 5-HT$_1$ and 5-HT$_2$ receptor activation, and hypoperfusion of the intestinal mucosa resulting from increased intralumenal pressure in patients with constipation or fecal impaction [121,155]. Although alosetron has been removed from the regular prescription market, it is available through a prescription program for use in female patients with severe refractory cases of diarrhea-predominant IBS.

Sodium polystyrene in sorbitol

Used to treat severe hyperkalemia, sodium polystyrene in sorbitol acts as a cation-exchange resin to decrease the serum potassium level. Rarely, ischemic colitis has been reported with both orally and rectally administered forms of the medication. It has been proposed that the hypertonicity of the sorbitol leads to rapid shifts of electrolytes, and both of these factors may be responsible for the colonic injury. Histologically, sodium polystyrene-in-sorbitol crystals are found adjacent to areas of necrosis in the colonic mucosa. However, the majority of patients are severely ill with separate risk factors for ischemic colitis, including renal failure and uremia [156,157].

Dextroamphetamines

Dextroamphetamine and other amphetamine medications, such as methamphetamine, are used in the treatment of attention deficit disorders and can lead to ischemic colitis [121]. Because amphetamines are sympathomimetic agents they can cause potent vasoconstriction, which is thought to be responsible for amphetamine-induced ischemic colitis [158]. The colitis typically resolves with withdrawal of the drug.

Pseudoephedrine

A sympathomimetic commonly used as a nasal decongestant, pseudoephedrine has been associated with ischemic colitis [159]. Colonic ischemia that results from use of pseudoephedrine is the result of vasoconstriction from its α-adrenergic agonist activity.

Vasopressin

Vasopressin and its analogues are potent vasoconstrictors traditionally used in the management of bleeding esophageal varices, and also employed for resuscitation following sepsis-induced shock. In its intravenous form, it acts by reducing splanchnic blood flow through vasoconstriction, which can induce colonic ischemia [160].

Digitalis

Digitalis is used in the treatment of cardiac arrhythmias and cardiac failure. Although digitalis has been noted to lead to

mesenteric vasoconstriction, it is also used in the treatment of conditions that predispose to an underlying low-perfusion state of the intestine, making it difficult to determine the true cause of the intestinal ischemia.

Neuroleptics

Case reports have associated neuroleptic medications, including tricyclic antidepressants, with the development of ischemic colitis [161].

Miscellaneous drug-induced colitides

Nonsteroidal antiinflammatory drugs (NSAIDs)

Nonsteroidal antiinflammatory drugs (NSAIDs) have long been associated with the development of intestinal pathology, most especially of the upper intestinal tract. The recognition of NSAID-induced colon toxicity has also increased but is still frequently underestimated. Up to 10% of all newly diagnosed colitis may be related to NSAIDs [162]. In one case–control study, 74% of patients with newly diagnosed colitis had a recent history of exposure to NSAIDS compared with 30% of controls [163]. The development of colitis in previously asymptomatic individuals has been associated with numerous NSAIDs such as ibuprofen, indomethacin (indometacin), diclofenac, enteric-coated aspirin, naproxen, phenylbutazone, piroxicam, and mefenamic and flufenamic acids [164]. Sustained-release formulations tend to lead most often to NSAID-induced colopathy. With rectal preparations, proctitis, rectal ulcers, and anorectal stenosis may result. Colitis induced by NSAIDs typically affects older adults, and no gender difference has been noted [164]. The most common presenting symptoms are diarrhea with or without occult bleeding or hematochezia; however, others may present with weight loss, fever, iron-deficiency anemia, elevated sedimentation rate, and hypoalbuminemia [165]. A rare few will experience symptoms of obstruction due to stricture or edema, which may lead to perforation. An increased risk of colonic diverticular perforation and the development of appendicitis has been associated with NSAIDs [67,164]. Ulceration and other inflammatory changes may be present in a focal or diffuse pattern throughout the colon, making it difficult to distinguish NSAID-induced colonic injury from IBD. Usage of NSAIDs may precipitate the initial flare of or worsen existing IBD [164,166,167]. Relapse of quiescent IBD was reported in 19 patients, the majority of whom had underlying ulcerative colitis, and relapse typically occurred within 1 week of NSAID ingestion [166].

The mechanism of injury to the intestinal mucosa may be due to multiple mechanisms. First, direct toxicity of the NSAID on the colonic mucosa may lead to increased intestinal permeability. Secondly, NSAIDs inhibit cyclooxygenase-1 (COX-1) and cyclooxygenase-2 (COX-2), thereby decreasing prostaglandin synthesis and increasing lipoxygenase production [67,168]. Because prostaglandins have cytoprotective and vasodilating effects on the intestinal lining, whereas lipoxygenase metabolites are proinflammatory and lead to vasoconstriction of the mesenteric blood vessels, increased mucosal inflammation and ulceration may result [67,168]. Both direct and indirect injury lead to increased intestinal permeability, which allows lumenal bacteria to translocate across the bowel wall and induce the production of inflammatory cytokines and nitric oxide [169,170]. Because evidence exists demonstrating that deficiency of prostaglandin production is not sufficient to alter short-term intestinal permeability or integrity, a combination of factors is thought most likely to lead to NSAID-induced colitis.

Endoscopic findings vary from mild mucosal erythema with granularity, erosions, or flat ulcerations to severe pancolitis [165]. Diaphragm-like strictures are common in the small bowel with NSAID use but may be seen in the colon as well, typically in the right colon, and can lead to obstruction [171]. Histology is nonspecific and similar to that seen in ischemic colitis.

Treatment consists of withdrawal of the NSAID and supportive care, which usually leads to healing. Surgery may be necessary in patients presenting with severe bleeding, obstruction, and perforation. Anecdotal reports of antibiotics and steroids causing improvement exist [165]. Rechallenge with NSAID therapy typically induces recurrence of colonic injury [164]. Patients with underlying bowel disease should avoid NSAIDs.

Gold

Gold salts have been used to treat collagen-vascular diseases, especially rheumatoid arthritis. Use of this agent has been associated with the development of colitis, likely caused by local drug toxicity. Up to 95% of gold is excreted in the stool, and biopsy specimens have demonstrated gold in the tissues [172]. Gold-induced colitis appears to have a female predominance. Presenting symptoms include watery or bloody diarrhea, abdominal pain, tenesmus, fever, and rash. Laboratory investigation may reveal leukocytosis, eosinophilia, anemia, and hypoproteinemia. Endoscopic studies reveal mucosal edema and friability, ulceration, and hemorrhage, usually in the rectosigmoid colon [172]. Histology may demonstrate acute and chronic inflammatory infiltrate, possibly with eosinophils. Treatment consists of withdrawal of the medication and supportive care [173].

Isotretinoin

An analogue of vitamin A used in the treatment of cystic acne, isotretinoin has been associated with acute colitis and reactivation of quiescent IBD. Cessation of the medication has been reported to result in improvement, and rechallenge causes recurrence [174]. The mechanism of injury is unknown.

Antibiotics

Ampicillin, amoxicillin, and erythromycin have been associated with a hemorrhagic colitis with bloody diarrhea, right-

sided colitis, absence of pseudomembranes, and absence of *C. difficile* toxin [175]. The pathogenesis is thought to involve overgrowth of intestinal flora other than *C. difficile*, such as *Klebsiella oxytoca* [176]. The colitis typically resolves rapidly on withdrawal of the offending agent.

Chemotherapeutic agents

Intestinal epithelial cells have a rapid turnover, which is disrupted by the administration of cytotoxic chemotherapeutic agents. The majority of chemotherapeutic medications, including cytosine arabinoside, methotrexate, 5-fluorouracil, cyclophosphamide, and cisplatin, have the potential to induce colonic mucosal injury and inflammation [177]. The severity of the colitis ranges from mild segmental colitis to fulminant ulcerative colitis with toxic megacolon [178]. If the cecum is involved, it is known as "neutropenic typhlitis." Most cases of chemotherapeutic-induced colonic injury occur in patients with severe leukopenia, specifically neutropenia, which allows bacteria to translocate across the intestinal mucosa. The presenting symptoms include fever, diarrhea, and abdominal pain, possibly with the presence of rebound abdominal wall tenderness and guarding [179]. Laboratory studies reveal leukopenia with neutropenia and, possibly, bacteremia. Treatment is supportive with cessation of chemotherapy, antibiotic therapy, and bowel rest. Use of granulocyte colony-stimulating factor (G-CSF) may aid in the reduction of neutropenia. When the neutropenia resolves, the colitis will improve. Complications can be severe and life-threatening and include hemorrhage, shock, and perforation.

Methyldopa

Methyldopa is an antihypertensive medication that can induce colitis [180]. All reported cases have improved with withdrawal of the medication, and readministration led to development of colitis in most cases.

Flucytosine

Flucytosine is an antifungal medication that has been associated with severe colitis, often complicated by perforation [181]. The pathogenesis is unknown but may be related to intestinal conversion of flucytosine to 5-fluorouracil, a metabolite used as a chemotherapeutic agent.

Diversion colitis

Diversion colitis is an inflammatory process that develops in segments of the colon that have been excluded from the fecal stream by surgical bypass, such as with a Hartmann pouch or mucous fistula. First noted by Morson in 1972 and named by Glotzer et al. in 1981, diversion colitis has since been noted in patients undergoing surgical diversion for IBD, cancer, diverticulitis, Hirschsprung disease, and trauma. The condition may develop months to years after diversion has occurred, and clinical, endoscopic, and histological findings appear to be progressive, with mild changes observed at 3 months [182] and more severe changes noted at 6–9 months [183,184] after diversion of the fecal stream has occurred. The majority of patients are asymptomatic but presenting symptoms can include mucoid or bloody discharge, abdominal cramping, and rectal pain [183]. Symptoms have been reported to be more prevalent in patients with IBD (89%) compared with cancer patients (23%) and patients with nonmalignant lesions (50%) [185]. The inflammatory process typically resolves in 3–6 months after restoration of the fecal stream [186].

Endoscopic evaluation may disclose mucosal edema, friability, granularity, mucous plugs, nodularity, and erosions with or without exudate [183]. In one prospective study, endoscopic evidence of inflammation was seen in 91% of patients, with mild changes noted in 52%, moderate changes in 44%, and severe changes in 4% [187]. Despite the large percentage of patients with moderate to mild changes, only 6% were symptomatic. With longer periods of diversion, inflammatory polyps, aphthous ulcerations, and strictures may develop [188]. Although the majority of patients are asymptomatic, up to 100% of patients exhibit histological changes of diversion colitis [182–185]. Within 3 months the majority of patients demonstrate lymphoid follicular hyperplasia with frequent germinal centers and a lymphoplasmacytic infiltrate within the lamina propria; in 60% of patients there is also mild crypt architectural distortion [187,189] (Fig. 59.5a,b). In more severe cases, crypt abscesses, Paneth cell metaplasia, aphthous erosions, ulcerations, mucinous granulomas, and occasional epithelioid granulomas may be noted [190]. However, transmural inflammation, large ulcers, and major crypt architectural distortion are rarely seen in diversion colitis.

Multiple theories exist for the development of diversion colitis. However, the most widely accepted hypothesis maintains that a lumenal deficiency of short-chain fatty acids (SCFAs) results in a lack of fuel for the distal colonocytes, which leads to a decrease in epithelial cell proliferation and resultant inflammation [191]. Roediger demonstrated that SCFAs, the metabolic products of carbohydrate and peptide fermentation by anaerobic bacteria, are the main fuel for the distal colonocyte [192]. There are multiple beneficial effects SCFAs on colonic epithelium, including downregulation of tumor necrosis factor-α (TNF-α)-induced cytokine expression [193]. Harig et al. demonstrated that excluded colonic segments contained minimal amounts of SCFAs and that infused carbohydrates were not metabolized to SCFAs [194]. This may be a consequence of the reduced number of anaerobic bacteria within the excluded segment of bowel [195]. Instillation of SCFA enemas once or twice daily induced remission, both clinically and histologically, in patients with diversion colitis [196]. It should be noted that SCFA therapy of diversion colitis is not always successful; therefore, other

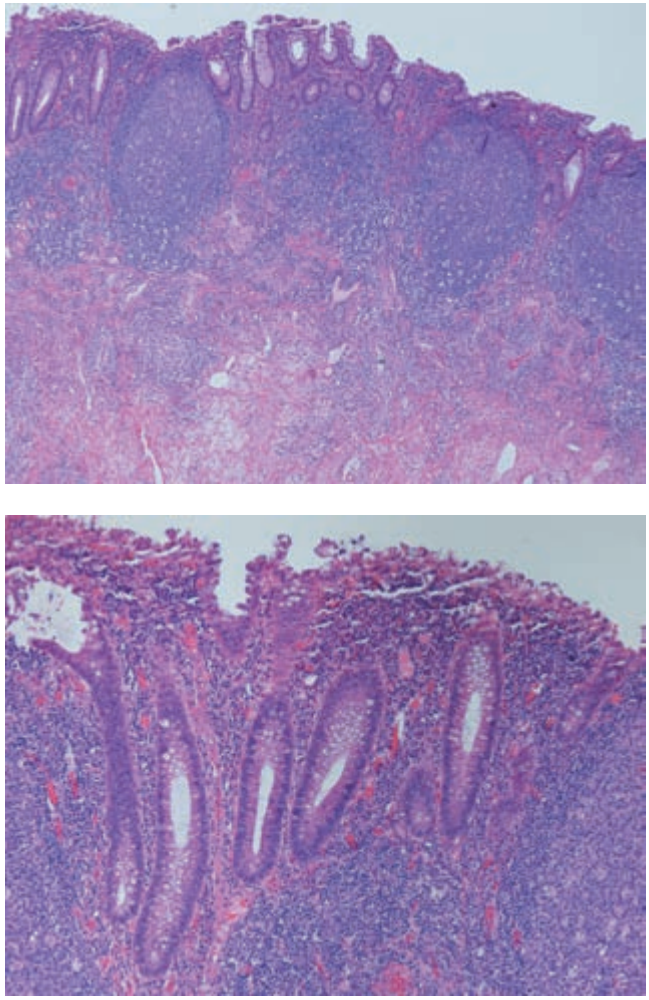


Figure 59.5 Diversion colitis is characterized by marked lymphoid hyperplasia, often compressing the crypt architecture **(a)**. There is no active cryptitis **(b)**.

hypotheses have been proposed regarding the pathogenesis of diversion colitis. A bacterial pathogenesis has been suggested but no single pathogenic organism has been isolated. An increase in nitrate-reducing bacteria (NRB) has been found in the defunctionalized colon, and a link between NRB and nitric oxide synthase-induced inflammation has been proposed [197]. Other possible mechanisms that have been suggested include the presence or lack of certain dietary factors, lumenal growth factors, or other bacterial metabolic products that may be necessary for optimal colonocyte function.

Diagnosis of diversion colitis is relatively straightforward in patients without presurgical intestinal inflammation, typically from underlying IBD. Flexible sigmoidoscopy with biopsies and lumenal aspirates for bacterial cultures, ova, parasites, and *C. difficile* toxin are useful to determine the extent of intestinal inflammation and to rule out other common causes of intestinal inflammation. Unless fistula or abscess is suspected, computed tomography (CT) and other radiographic examinations are not helpful. After resection of a colonic adenocarcinoma, the excluded segment of bowel must be included in regular colon screening, as polyps and recurrent adenocarcinoma may be a source of bleeding from the excluded bowel [185].

Differential diagnosis is typically straightforward. Diversion colitis lacks major crypt architectural distortion and is generally milder than IBD.

The majority of patients with diversion colitis are asymptomatic, therefore, therapy is rarely indicated. In the symptomatic patient, the preferred treatment is surgical restoration of intestinal continuity if possible. In those patients where intestinal restoration is not possible, treatment with SCFA enemas (60 mmol/L acetate, 40 mmol/L butyrate, 30 mmol/L propionate) administered twice daily per rectum or mucus fistula for 4 weeks and then decreasing to once or twice weekly may induce remission [194]. Mesalamine enemas have been reported to be helpful in a small number of patients [198].

Diverticular colitis

Diverticular disease-associated colitis (DAC) occurs in patients with diverticulosis of the sigmoid colon and is characterized by a chronic focal inflammation of the interdiverticular lumenal mucosa. First recognized in 1983, it is also known as diverticular colitis, crescentic fold disease, isolated sigmoiditis, and segmental colitis associated with diverticula (SCAD) [199]. Because the macroscopic and microscopic changes of diverticular colitis may be indistinguishable from those seen with IBD [200], it can be difficult to separate DAC from coexistent diverticulosis and IBD. Reports of coexistent disease are not uncommon. Diverticulosis is highly prevalent in Western populations, affecting up to 60% of people aged over 70 years [201], and Crohn's disease has a bimodal distribution, with a second peak occurring later in life [202]; therefore, the association of these two disorders is not unexpected [203]. The majority of patients with diverticulosis and IBD-related segmental colitis also have IBD elsewhere within the digestive tract. Resection of the segment demonstrating diverticular involvement effectively cures diverticulosis in such patients, but will not protect against further flares of the underlying IBD [204]. Nevertheless, there are patients with segmental colitis localized to an area of sigmoid diverticulosis in whom colitis does not recur after resection of the involved areas of colon. McCue and colleagues, for example, reported four patients who underwent segmental resection of the sigmoid colon for diverticulosis and Crohn's disease limited to the sigmoid colon. No patient developed recurrent Crohn's disease during a mean follow-up period of 22 months [205]. Gledhill and Dixon reported 11 patients diagnosed with both Crohn's disease and sigmoid diverticulosis or diverticulitis [206]. Three of the patients had Crohn's disease elsewhere in the digestive tract, but the remaining eight patients remained

free of recurrence over a follow-up of 1–10 years. In a prospective study of 23 patients with the endoscopic and histological diagnosis of segmental sigmoid colitis, only 3 patients developed unequivocal features of ulcerative colitis, whereas the remaining 20 patients had no extension of colitis over a 4-month to 8-year follow-up [203]. Goldstein et al. reported 29 patients who underwent sigmoid resection for Crohn's disease with diverticular disease [207]. Four had Crohn's prior to development of diverticular disease, but only 2 of the remaining 25 patients developed Crohn's disease over a median follow-up of 6 years. These observations suggest that colitis accompanying sigmoid diverticular disease is not likely to be classic IBD and is a separate disorder. The incidence of DAC ranges from 0.3% to 1.4% [203,208], and affected patients have a mean age at diagnosis of 63–69 years [203,206,208]. No gender predominance has been observed in diverticular colitis. Although some patients may be asymptomatic, with inflammation noted incidentally at the time of endoscopy or biopsy, up to 83% of patients may present with hematochezia [203], and other symptoms include cramping abdominal pain, diarrhea, and tenesmus. As stricture formation is rare, it is unusual for patients to present with obstruction.

The etiology of diverticular colitis is unknown. Left-sided diverticula are typically pseudodiverticula (false diverticula), which are outpouchings of the colonic mucosa and submucosa through the muscularis propria at points where blood vessels penetrate to supply the mucosa and submucosa [209]. Fecal stasis within and around the diverticula may alter local bacterial flora, contributing to the inflammation in diverticular colitis [200]. Peridiverticular mucosal prolapse may lead to diminished blood flow to segments of the colon affected by diverticulosis, initiating mucosal injury and allowing bacterial translocation across the mucosa. Intimal hyperplasia of blood vessels could limit local blood supply and contribute to a low-perfusion state, leading to ischemic injury of the mucosa surrounding the diverticula. Finally, activated immune cells in diverticulitis produce nitric oxide and could damage the intestinal mucosa by formation of oxygen radicals [210]. Complications of diverticulosis, such as subserosal peridiverticulitis and abscess formation, may lead to mass effect on the colonic wall and induce a localized inflammatory response.

Grossly, diverticula are universally present. Colonoscopic findings with diverticular colitis include mucosal edema, erythema, and friability confined to the distal descending and sigmoid colon [203]. The terminal ileum and remainder of the colon are unaffected; in particular, the rectum is spared and may aid in differentiating diverticular colitis from untreated chronic ulcerative colitis. Distribution of mucosal inflammation can be patchy or diffuse. The affected length of colon may range from 5 cm to 25 cm [203]. Focal bowel wall thickening, stricture formation, cobblestoning of the mucosa, and creeping serosal fat have been noted on resection specimens [206,208]. Histologically, diverticular colitis may be indistinguishable from IBD. Cryptitis, crypt abscess formation with distortion of crypt architecture, mononuclear infiltrate within the lamina propria, transmural lymphoid aggregates, transmural granulomatous inflammation, and granulomatous vasculitis have all been described. Makapugay and Dean, for example, found plasmacellular and eosinophilic expansion of the lamina propria in 100% of patients, neutrophilic cryptitis in 100%, crypt abscesses in 61%, distorted crypt architecture in 87%, surface epithelial sloughing in 61%, Paneth cell metaplasia in 48%, and granulomatous cryptitis in 26% [203]. The granulomatous inflammation is often a foreign-body reaction to mucin extrusion due to crypt rupture [203], although others have observed that many of the granulomas are found not near inflamed diverticula but throughout the entire intestinal wall and in the serosal fat, indicating that they represent "true" granulomas [206,208]. In one series, regional lymph node granulomas were noted in 75% of patients, effectively ruling out foreign body reaction as a cause of the granuloma [208].

Appropriate treatment rests on ruling out complications of diverticular disease, such as abscess formation and perforation, and ruling out other causes of segmental colitis, such as IBD, infection, and medication-induced colitis. Diverticular colitis can be distinguished from untreated chronic ulcerative colitis by the sparing of the rectal mucosa, which should be biopsied in all patients presenting with left-sided colitis [203]. Because diverticular colitis may exhibit the "classic" findings of Crohn's disease – transmural inflammation, fissures or fistulae, and granulomas – it may be impossible to distinguish diverticular colitis from Crohn's disease on endoscopic biopsies as well as segmental colectomy specimens [207]. As noted above, many patients exhibiting changes consistent with Crohn's disease only in the area involved with diverticulosis will not experience a recurrence of colitis after surgical resection, suggesting that the majority of patients with a dual diagnosis probably have diverticular colitis not Crohn's disease [207,208]. In this setting, unless the patient has involvement of the perianal area or other segments of bowel usually involved with Crohn's disease, the diagnosis of IBD should not be made because this may have greater implications for the patient, such as increased risk of colorectal cancer. Conservative treatment has been shown to be effective in up to 60% of patients and consists of a high-fiber diet, antibiotics, sulfasalazine, 5-aminosalicylic acid, and, in some cases, corticosteroids [203]. If diverticulitis is present, immunosuppression may be contraindicated, and bowel rest, intravenous hydration, and antibiotics may be warranted. Surgical therapy is warranted in those patients with complicated diverticulitis, such as perforation and intraabdominal sepsis. Segmental resection of the colon may also be warranted in patients with obstruction, stricture of unknown etiology, and refractory symptoms, such as hematochezia with anemia [203].

Colonic ulcers

Colonic ulceration occurring in otherwise healthy colonic mucosa may be associated with a number of conditions. Although the underlying etiology may vary, the presenting symptoms are strikingly similar and include abdominal pain, hematochezia, and mucopurulent rectal discharge. Diarrhea can occur if a large amount of colonic surface area is affected, but is rare with isolated ulceration. A careful history and physical combined with endoscopic and histological evaluation will aid in the differentiation of these conditions.

Isolated nonspecific colonic ulceration

First described by Cruveilheir in 1832, benign nonspecific colonic ulcerations occur infrequently. Ona and colleagues reported 127 patients with nonspecific colonic ulceration and determined that onset occurs at an average age of 45 years (range 8–84 years) and noted a slight female predominance (55%) [211]. Although nonspecific colonic ulcers may occur anywhere in the colon, they are most often found in the cecum (67%) and ascending or transverse colon (18%). These ulcers are usually solitary, round, or oval with sharply demarcated margins surrounded by normal colonic mucosa, and are located on the antimesenteric side of the intestinal lumen [211–214]. Biopsies are nonspecific and demonstrate both acute and chronic inflammation [211].

The pathogenesis of nonspecific colonic ulceration remains unknown, and other causes of colonic ulceration, such as inflammatory bowel disease, infection, medication-induced ulceration, vasculitis, fecal stasis, rectal prolapse, renal failure, and malignancy, must be carefully ruled out before a diagnosis of nonspecific colonic ulceration can be made. In a case series of 26 patients with nonspecific erosions and ulcerations of the colonic mucosa, the most common causes were previous abdominal irradiation and ischemia [215]. Vascular abnormalities, including thickening of the vascular walls and microvascular thrombosis, have been described in the area surrounding the ulceration, which may implicate a localized form of ischemia [212–214]. The ischemic hypothesis is supported by the location of the ulcers on the antimesenteric border, the shallow granulation base, and the sometimes circumferential orientation of the ulcers. However, ischemia typically occurs in the watershed area of the colon, usually in the descending colon and sigmoid colon. This would fail to explain why the majority of nonspecific colonic ulcerations are right-sided. Cecal diverticulosis has been proposed as a cause of nonspecific colonic ulceration as a result of the observation that 5 out of 10 cases of cecal ulceration had cecal diverticula [216]. However, cecal diverticula typically occur on the mesenteric border whereas ulcerations are most often found on the antimesenteric border of the cecum, which casts doubt on this hypothesis. In addition, the sigmoid colon has a much higher prevalence of diverticula when compared with the cecum, yet is not a common site for nonspecific colonic ulceration. It has also been proposed that a disturbance in acid–base balance in the ileocecal region is involved in the pathogenesis of nonspecific cecal ulcers or that digestive enzymes presented to the cecal mucosa lead to ulceration [212]. Medications such as NSAIDs, corticosteroids, and oral contraceptives [211,214], as well as foreign body trauma [211], infection [212,217], and toxins, have each been implicated in the formation of colonic ulcers. It is likely that multiple causes exist for the development of nonspecific colonic ulceration.

The most common presenting symptoms are abdominal pain in the right lower quadrant (50%) and hematochezia (33%) [211]. Other features include fever and leukocytosis. A palpable abdominal mass was noted in up to 16% of patients and was present with transverse- or left-sided colonic ulcerations, presumably due to associated edema of the colon. Such an inflammatory mass has potential to obstruct the lumen of the intestine and may mimic a malignancy on diagnostic work-up. Perforation presenting with an acute surgical abdomen occurred in about one-fifth of patients [211].

A history is typically unhelpful unless the patient has overt rectal bleeding or signs and symptoms of obstruction. Physical examination may be normal or may disclose abdominal pain or mass on rectal examination. In the past, this diagnosis was made at the time of surgery for a perforating complication, which was noted in 82% of patients in a retrospective review [213]. Colonoscopy, the diagnostic test of choice, has facilitated early diagnosis and more aggressive medical management.

The differential diagnosis for nonspecific colonic ulceration is broad and the diagnosis is one of exclusion. An infectious cause of ulceration must be ruled out, especially in immunocompromised hosts, although typically an infectious etiology leads to the formation of multiple ulcerations. Infections that can cause colonic ulceration include cytomegalovirus, tuberculosis, *Yersinia enterocolitica*, *Entamoeba histolytica*, and *Salmonella typhi*. Tuberculosis of the colon usually causes nodularity and deformity of the ileocecal valve whereas nonspecific colonic ulceration usually does not produce these findings [214,218]. Inflammatory bowel disease should be excluded and other clinical features, such as the involvement of other areas of the intestinal tract and the appearance of the ulcers, may be helpful in differentiating nonspecific colonic ulceration from Crohn's disease [214]. Ischemic ulcers are usually located within the watershed areas of the colon, namely the rectosigmoid junction and the splenic flexure [211]. Solitary rectal ulcers are not found in the right colon and have a distinct microscopic appearance, which is described later in this chapter. Stercoral ulcers are normally caused by fecal impaction with resultant pressure necrosis and are most commonly found within the sigmoid area. The diagnosis of malignancy may be difficult to distinguish on investigations from nonspecific colonic ulcers, especially

if a mass effect is associated with the ulcer, and must be ruled out histologically. Vasculitis due to Behçet disease, systemic lupus erythematosus, and Churg–Strauss syndrome [211,219] have rarely been associated with nonspecific colonic ulcers and, if the clinical scenario is fitting, should be ruled out.

Uncomplicated colonic ulcers may be followed endoscopically every 4–6 weeks, with multiple biopsies being taken at the time of each endoscopy to document healing and rule out malignancy and infection. Surgery remains the mainstay of therapy for nonspecific ulcers complicated by bleeding, failure to heal on endoscopic examination, abscess formation, and perforation. Oversewing of the ulcer, local excision of the ulcer, and right hemicolectomy have been performed for surgical therapy of nonspecific colonic ulceration.

Dieulafoy-type colonic ulceration

In 1897 Georges Dieulafoy described three otherwise asymptomatic patients who exsanguinated due to a minute gastric ulceration overlying a submucosal artery. He termed this lesion *exulceratio simplex*. Although this type of ulceration most commonly occurs in the upper third of the stomach, lesions virtually identical to Dieulafoy's initial description have been reported to occur throughout the intestine [220,221]. Colonic Dieulafoy lesions are exceedingly rare. In the largest published series [221], only five colonic Dieulafoy lesions were noted among 3059 patients presenting with gastrointestinal bleeding. Presentation is usually one of acute massive rectal bleeding accompanied by severe hemodynamic instability. Pathophysiology is not known, although it has been proposed that pulsations of the large-caliber submucosal artery lead to erosion of the overlying mucosa [220]. Diagnosis may prove problematic as lesions are notoriously difficult to see on endoscopy because of the intermittent nature of the arterial bleeding coupled with the lack of inflammation surrounding the mucosal ulceration. Often, the lesion may not be bleeding at the time of the endoscopy and it may resemble a pseudopolyp, although once the extruded tissue is removed, the resulting hemorrhage is characteristic of a Dieulafoy lesion. Doppler-endoscopy may be helpful to identify arterial flow within a lesion [222]. A pulsating red spot covered with clot should raise suspicion for a Dieulafoy lesion of the colon [217]. If endoscopic localization of the lesion is unsuccessful, selective mesenteric angiography may be helpful [223]. Angiography is most useful when the patient is actively bleeding. Colonic lesions are grossly and histologically identical to classic gastric Dieulafoy lesions, demonstrating a single mucosal defect extending no deeper than the upper submucosa. Endoscopic therapies such as sclerotherapy, electrocautery, and hemoclipping have led to successful control of bleeding in a number of reports, and endoscopic intervention should be attempted if the condition of the patient allows [221,224]. Surgical resection of the affected area remains the definitive therapy.

Stercoral ulcer (Huntley syndrome)

A stercoral ulcer is a colonic ulceration caused by ischemic pressure necrosis resulting directly from a fecal (stercoraceous) mass or impaction. This ulceration may lead to perforation and peritonitis. Risk factors for the development of both stercoral ulceration and perforation include: chronic constipation; factors or medical conditions that predispose to constipation, such as confinement to a long-term care facility; use of constipating medications, such as narcotics; hypothyroidism; colonic strictures; neoplasms; renal failure; and transplantation. In these patients, fecalomas (masses of hard stool) may have been present for years and may have laminations and calcification [225]. Less than 100 cases have been reported in the literature. Most stercoral ulcers occur in the rectosigmoid colon [225,226]. Perforating stercoral ulcers are typically located on the antimesenteric border of the sigmoid or rectosigmoid colon, and the diameter of the perforation usually exceeds 1 cm [225,226].

Surgical resection is the definitive therapy of both perforated and nonperforated stercoral ulcers. The major cause of mortality is uncontrolled sepsis [225]. Resection of the involved area with primary anastomosis may be performed in the absence of perforation, whereas resection with end ileostomy and Hartmann pouch or mucous fistula may be performed for those with stercoral perforation.

Solitary rectal ulcer syndrome and colitis cystica profunda

Solitary rectal ulcer syndrome

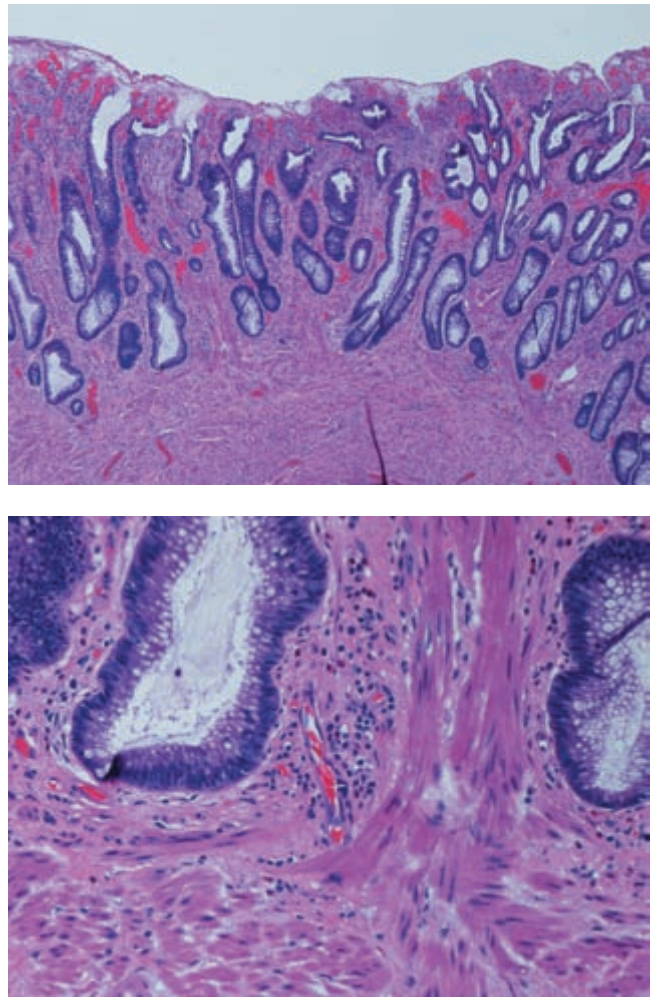
Solitary rectal ulcer syndrome (SRUS) was first described in 1830 by Cruveilheir, but it was not until the 1969 review by Madigan and Morson, which reported on 68 cases and established diagnostic criteria, that the knowledge of this disease entity became widespread [227]. An uncommon disorder, it affects 1 in 100 000 [228]. It typically affects young adults, presenting in the third or fourth decades [229].

Presenting symptoms are alteration of bowel habits, difficult evacuation, rectal bleeding, and mucous discharge. Tenesmus, constipation, straining, incomplete evacuation, and lower abdominal pain have been reported in 70%–90% of patients [230,231]. Rectal bleeding occurs in up to 89% of patients [230] and can range from minimal to massive blood loss [232]. Overt rectal prolapse and fecal incontinence are less common. Interestingly, in one large review, 26% of patients with endoscopic discovery of a solitary rectal ulcer were asymptomatic [230].

The etiology and underlying pathophysiology of SRUS are not clear. Local trauma due to prolapse of rectal mucosa, self-digitation, and stool impaction, as well as ischemic injury have been implicated in the pathogenesis of SRUS [233]. However, 50% or more SRUS patients deny digital manipulation of the rectum and, at times, the ulcer is located in an area too proximal in the rectum to be reached by insertion of a finger. The incidence of mucosal or full-thickness rectal

prolapse ranges from 13% to 100% in published series of SRUS patients [230]. Salzano et al. noted that 52% of patients experienced either mucosal prolapse or external rectal prolapse [234]. Ischemic injury can occur as a consequence of impacted stool, pressure on the rectal mucosa due to contracted puborectalis muscle or overactivity of the external anal sphincter [235], use of suppositories such as ergotamine [236], and a history of radiation to the rectal area [237]. A combination of rectal prolapse and a high fecal voiding pressure (caused by overactivity of the external anal sphincter or failure of puborectalis relaxation during defecation) has been theorized to cause both trauma and localized ischemic injury to the rectal mucosa resulting in ulceration [235]. It appears that SRUS is a benign condition but, rarely, an underlying carcinoma may be present with SRUS.

Diagnosis is based on appropriate symptomatology combined with endoscopic and histological findings consistent with SRUS. Obtaining a proper history is crucial in excluding more serious or potentially life-threatening disorders, such as malignancy, infection (amebiasis, lymphogranuloma venereum, syphilis), and chronic intestinal ischemia. Other diagnoses that may present in a similar fashion to SRUS include inflammatory bowel disease, NSAID-induced or ergotamine-induced ulcerations, and endometriosis. Despite the term solitary rectal ulcer syndrome, patients may present with multiple ulcers, polypoid lesions, or simply erythematous mucosa [228]. Therefore, it is not surprising that its endoscopic appearance is variable. In classic SRUS, a single, well-demarcated ulcer measuring up to 5 cm will be located at 6–10 cm from the anal verge on the anterior rectal wall in 68%–95% of cases [228,230]. However, given the variable endoscopic appearance, it is imperative to obtain biopsies of the affected area to rule out other disorders, such as malignancy. Defecography can be helpful in demonstrating the presence of internal and external rectal prolapse as well as colonic intussusception, incomplete rectal emptying, and nonrelaxing puborectalis. This examination is typically utilized when operative intervention is considered [238]. Barium enema and anorectal manometry do not appear to be useful in the diagnosis of SRUS. Transrectal or endoscopic ultrasound may be used to rule out invasive malignancy and assess the extent of disease in SRUS patients [233]. Specific histological criteria as defined by Madigan and Morson are used to establish the diagnosis of SRUS [227]. Fibroblasts, smooth muscle, and collagen replace the lamina propria with associated hypertrophy and disorganization of the muscularis mucosa, termed fibromuscular obliteration of the lamina propria (Fig. 59.6). Erosion of the mucosal surface as well as distortion and displacement of the mucosal glands into the submucosa may be seen. Diffuse collagen infiltration of the lamina propria is seen almost exclusively in SRUS and can be used to differentiate this disorder from inflammatory bowel disease and chronic ischemic colitis [239]. Occasionally, cystic submucosal glands have been noted, and this has led to speculation that colitis cystica profunda and SRUS are identical or closely related syndromes.



(a)

(b)

Figure 59.6 Solitary rectal ulcer syndrome (prolapse-related injury). **(a)** Thickened mucosa with surface inflammation and erosion. **(b)** The base of the mucosa shows thickened, frayed bands of smooth muscle typical of prolapse injury.

Treatment of SRUS depends on the presence or absence of symptoms, the presence or absence of rectal prolapse, and the type of lesion in the rectum. Treatment can be divided into medical and surgical options, although there are few data regarding the efficacy of medical therapies. Treatment may not be necessary in asymptomatic patients, and spontaneous resolution of SRUS has been reported. Patients with polypoid lesions are usually younger and less symptomatic and often respond to conservative medical therapy [230]. Bowel retraining, high-fiber diet, and bulk laxatives have all been used with variable success rates. Fibrin glue has shown promise with topical application to the ulcer leading to healing in 2 weeks [240]. Surgery with abdominal rectopexy is advised for patients with significant rectal prolapse or those refractory to medical therapy. One group demonstrated

complete resolution of rectal prolapse in 95% of patients with both prolapse and SRUS [238].

Colitis cystica profunda

Colitis cystica profunda is a rare condition in which variably sized mucus-filled cysts are found within the submucosa of the lower intestinal tract, most often as a solitary lesion in the rectum [241]. The cysts are typically large, located below the muscularis mucosae, and may be mistaken for a malignant process based on presentation of the patient and radiographic and endoscopic appearances. Similar cysts may be found in the small bowel, where the entity is then termed "enteritis cystica profunda." The distribution of colitis cystica profunda may be localized, segmental, or diffuse [241,242]. Presenting symptoms are most commonly diarrhea, hematochezia, and mucus discharge per rectum [241]. Bulky cysts or fibrotic lesions may lead to intestinal obstruction, although this is rare. Colitis cystica profunda does not have proven malignant potential but adenocarcinoma has been found adjacent to the submucosal cysts [243]. The pathogenesis is unknown.

Physical examination is variable and depends on the distribution of the disease. The localized form can usually be detected at the time of digital rectal exam, which reveals one or more smooth, firm masses not adherent to the underlying muscle layer, thickened rectal wall, or stenosis. Lesions are usually found within 12 cm of the anal verge on the anterior rectal wall. At colonoscopy, findings range from normal to mucosal edema, erythema, friability, or ulceration overlying a polypoid submucosal mass. An umbilication may be noted on the lumenal surface of the cyst as these lesions typically communicate with the lumen through mucosal openings. Large cysts may be present, and multiple cysts can coalesce to form a mass measuring up to 3 cm. Rarely, this mass may obstruct the lumen of the bowel. Rectal stricture or prolapse may be noted. It can be difficult to differentiate endoscopically the findings of colitis cystica profunda from other disorders such as IBD, pseudopolyps, submucosal lipomas, and adenocarcinoma. Because the mucosal biopsies obtained by endoscopy are shallow, they may be inadequate for definitive diagnosis of colitis cystica profunda. Surgical excision may be necessary to make a definitive diagnosis. Biopsy demonstrating the typical histological features and the absence of malignant findings is necessary to make a definitive diagnosis of colitis cystica profunda. Microscopically, the submucosal layer is thickened by cysts, which occasionally extend into the muscularis propria and serosa (Fig. 59.7). Care must be taken to differentiate this disorder from well-differentiated mucin-producing adenocarcinoma. Cysts might be lined with a well-differentiated epithelial lining or have no lining at all. The lamina propria is usually replaced by collagen and disoriented smooth muscle cells. The cysts are typically bordered by normal colonic mucosa, but adjacent mucosal edema, superficial ulceration, acute and chronic inflammation, pseudomembranes, and distorted crypt architecture may be present.

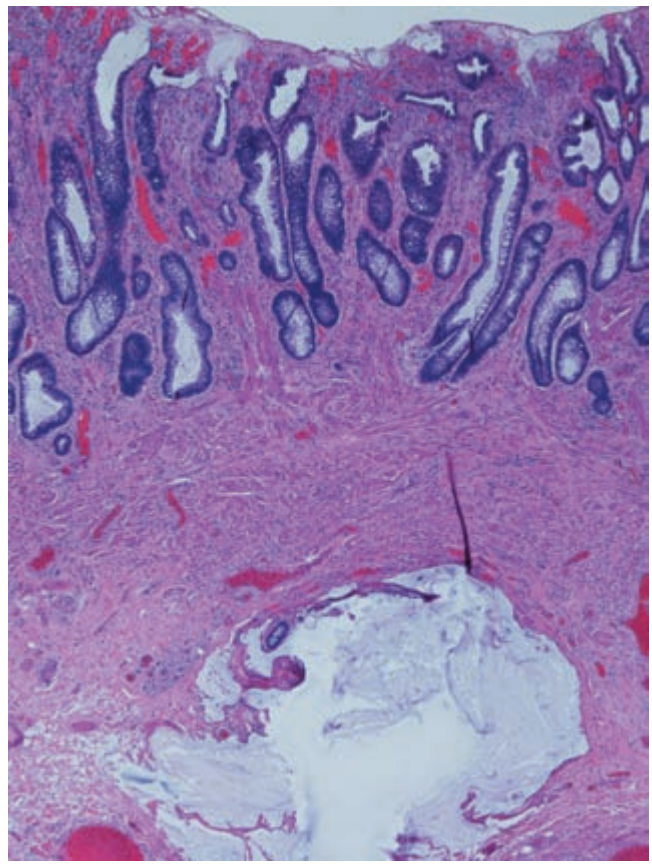


Figure 59.7 Colitis cystica profunda. The mucosa shows prolapse-related injury. There is displaced mucin and epithelium in the submucosa.

The majority of symptomatic patients have been treated with local surgical excision of cysts and ulcers. If localized colitis cystica profunda is present, transanal excision is usually adequate [241]. In the setting of rectal prolapse, repair may lead to resolution of the cysts. Although colonic resection is usually unnecessary, it may be appropriate for cases of diffuse involvement, severely symptomatic cases, and those cases where cysts lead to intestinal obstruction.

Pneumatosis cystoides intestinalis

Pneumatosis cystoides intestinalis is an uncommon condition characterized by gas-filled cysts within the wall of the intestine, typically within the subserosa and submucosa of the small and large bowel. Cysts occur most commonly in the small bowel (42%), in the large bowel less often (36%), and diffusely in both the small and large bowel in the remainder (22%) [244]. These gas-filled cysts are also rarely found in the stomach and other extraintestinal structures such as the omentum, mesentery, and lymph nodes [245]. Pneumatosis is a sign not a disease. Clinical presentation and history should be considered when attempting to determine the etiology

of the pneumatosis. Pneumatosis has been associated with more fulminant conditions such as bowel infarction, perforation, necrotizing enterocolitis, and pseudomembranous colitis. Pneumatosis cystoides intestinalis can be classified as either primary (idiopathic) or secondary. Secondary pneumatosis has been associated with both primary gastrointestinal disorders and extraintestinal conditions, most commonly with chronic obstructive pulmonary disease, collagen vascular diseases (mixed connective tissue disease, scleroderma, systemic lupus erythematosus, dermatomyositis, polymyositis), cystic fibrosis, intestinal obstruction, pseudoobstruction, pyloric stenosis, inflammatory bowel disease, status post-jejunoileal bypass, sigmoid volvulus, and iatrogenic induction by endoscopy or surgery [246–249]. Pneumatosis has occurred in patients with late-stage AIDS, which appears to be associated with cryptosporidial diarrhea, and tends to involve the right colon and cecum [250]. Reports of association with rotavirus in children and the presence of spirochetes within the cysts can be found in the literature [251,252]. Patients with hematological malignancies undergoing chemotherapy have developed pneumatosis during times of leukopenia, thought to be due to damage of the intestinal mucosa by chemotherapeutic agents or steroids [247]. Medications have also been associated with secondary pneumatosis. Chloral hydrate medications and exposure to trichloroethylene, both of which are chemically similar to chloroform, have been implicated in the development of pneumatosis cystoides intestinalis [253]. In patients with IBD and transplantation, steroids have been linked to the development of pneumatosis intestinalis [248]. A case–controlled study was performed comparing 50 patients with Crohn's disease who underwent CT scanning to rule out abscess, with 50 control patients without inflammatory bowel disease [248]. In the Crohn's disease group, 12% were found with pneumatosis whereas none in the control group had evidence of pneumatosis by CT scan. Corticosteroid treatment was significantly related to development of pneumatosis ($P = 0.025$) [248]. Pneumatosis occurs in patients with a history of cardiac, liver, renal, or bone marrow transplantation [254,255]. In the setting of systemic illness or complication, it is a poor prognostic sign [256]. Only 15% of cases are idiopathic [245]. Pneumatosis can occur at any time from infancy to adulthood, but the majority of cases occur between 30 and 50 years of age [257].

Pneumatosis is typically found incidentally on radiographs, endoscopic evaluation, or at the time of laparotomy as the majority of patients are asymptomatic or minimally symptomatic. The most common symptoms are diarrhea, rectal bleeding, and mucous discharge [246]. Patients have also identified constipation, abdominal pain, weight loss, and tenesmus as presenting symptoms of the condition [246]. Secondary pneumatosis intestinalis typically affects the small bowel and ascending colon, whereas the left colon is typically affected in idiopathic cases [258]. The sigmoid colon has been found to be redundant in 80% [246], and it remains unknown if this redundancy plays a role in the formation of pneumatosis. Infrequently, the rectum is involved [257]. Cysts can vary in size from millimeters to a few centimeters, and are typically found in clusters. Complications are rare and include pneumoperitoneum, obstruction, volvulus, intussusception, hemorrhage, and perforation [259].

In up to two-thirds of patients, diagnosis can be made on the basis of plain abdominal films, in which the cysts appear as curvilinear, linear, cystic, or grape-like clusters within the bowel wall [260]. In addition, free intraperitoneal air and retroperitoneal air may be noted. Decubitus and upright positions may help to distinguish intralumenal air from pneumatosis intestinalis. Barium contrast studies show multiple radiolucent lumenal filling defects interposed between the barium column and the outer bowel, and can help confirm location within the bowel wall [261]. However, on barium enema, pneumatosis can be misdiagnosed as intestinal polyps, pseudopolyposis, and intramural hematomas [262]. CT scanning is reported to be more sensitive in the detection of intramural gas than plain abdominal radiographs [263,264]. On CT the intramural gas of pneumatosis appears parallel to the bowel wall and can be located on the dependent aspect of the bowel and does not contain air–fluid levels. In addition, CT demonstrates thickened bowel wall, free intraperitoneal air, hepatic portal venous gas, intralumenal gas, and mesenteric gas. The presence of portal venous gas or mesenteric gas with pneumatosis is highly suggestive of bowel infarction. Pneumatosis may be misdiagnosed as stool mixed with colonic gas. Magnetic resonance imaging (MRI) has been used to identify pneumatosis, which is suggested by finding circumferential collections of air adherent to or within the bowel wall. Endoscopic evaluation with flexible sigmoidoscopy or colonoscopy reveals multiple, round, pale to bluish, submucosal polypoid masses covered with normal mucosa protruding into the bowel lumen [265]. Diagnosis can be confirmed by collapse of the cysts on attempted biopsy or puncture, which often produces a hissing or popping sound [256]. Caution must be exercised when attempting to biopsy one of these nodules as perforation of the bowel has been reported [266]. Endoscopic ultrasound has been utilized in a small number of patients to confirm the presence of submucosal cysts [267]. Histology of these cysts demonstrates the absence of a true epithelial lining but instead they are partially lined with histiocytes and foreign-body giant cells [268]. At times, the cysts have been found to be lined with a single layer of mesothelium or endothelium [268]. Inflammation with neutrophils, eosinophils, plasma cells, lymphocytes, and epithelioid granulomas has been noted as well.

The significance of pneumatosis is directly related to the overall clinical condition of the patient. In asymptomatic patients, treatment is indicated only for any associated illness(es) as the cysts typically resolve spontaneously. In fact,

no treatment is necessary in 85% of asymptomatic patients, and up to 50% of cases will resolve spontaneously [245,269]. High-flow oxygen and hyperbaric oxygen have been used with success in the treatment of pneumatosis cystoides intestinalis. Oxygen therapy is based on the hypothesis that the high concentration of inhaled oxygen increases the partial pressure of oxygen in the bloodstream relative to hydrogen and nitrogen, thus causing resorption of the gases from the cysts into the bloodstream [257]. High-flow oxygen, delivering 55%–75% oxygen by a venturi mask and used to achieve an arterial oxygen partial pressure of 200–350 mmHg, has been shown to lead to resolution of cysts. One report showed that oxygen delivered at lower concentrations (40%) was also successful [270]. Treatment should be continued for at least 5–7 days and for 2 days after resolution of symptoms [270,271]. Unfortunately, relapse is common with the use of oxygen (50%–78%), although patients do appear to respond to a repeated course of oxygen therapy [246]. Hyperbaric oxygen administered at 303.975 kPa for 45–60 min twice daily for up to 30 days has been successfully used as well [272,273]. Metronidazole has been used in the treatment of pneumatosis on the premise that anaerobic bacteria are responsible for the formation of the gas-filled cysts [257,274]. Use of an elemental diet has also been shown to be helpful in the treatment of pneumatosis [275]. Although most patients with benign pneumatosis can be managed medically, a rare few will require surgical resection for symptomatic relief. Surgery typically involves a partial colectomy, yet this does leave a potential for recurrence. There are reports of successful management with ileal pouch–anal anastomosis [276]. Surgical intervention is typically warranted in those patients with fulminant pneumatosis.

Endometriosis

Endometriosis is a common disorder that occurs in approximately 15% of menstruating women [277], although the prevalence may be higher due to the presence of nonpigmented endometriosis [278]. Endometriosis can involve sites distant from the uterus and ovaries. Endometrial involvement of the intestinal tract occurs in 15%–37% of patients with pelvic endometriosis and is often asymptomatic [279–281]. Within this group, the rectosigmoid colon is most commonly affected (95%), with more proximal locations, such as the appendix (10%) and the terminal ileum (5%), involved less frequently [280]. In a review of 7200 women with endometriosis, the small bowel was affected in only 38 patients [282]. The mean age of diagnosis is between 25 and 29 years [277], and most patients who undergo surgical resection of intestinal endometriosis are between the ages of 28 and 56 [283]. The usual indication for intestinal resection is chronic partial obstruction, due to the chronic inflammation and fibrosis from endometrial intestinal implants or due to a mass effect of the submucosal implant causing compression of the lumen [284]. Colonic obstruction due to endometriosis is rare and usually occurs in postmenopausal women treated with hormone replacement therapy or tamoxifen [285].

Symptoms of pelvic endometriosis, such as dysmenorrhea, dysfunctional uterine bleeding, dyspareunia, and infertility, are more prominent than the intestinal symptoms. Those patients with serosal implants may present with abdominal pain or cramping, abdominal bloating, low back pain, localized tenderness, palpable nodules on rectovaginal exam, change in stool caliber, diarrhea, and rectal bleeding [283]. Hematochezia is noted in 3%–33% of patients undergoing surgical resection of the intestine due to endometriosis [284,286]. Intestinal symptoms do not follow the cyclic changes with the menstrual cycle, primarily because the intestinal lesions of endometriosis are not strongly influenced by hormonal changes (i.e., fibrostenosis of the lumen, and compression of the lumen due to the endometrioma) [284]. Acute appendicitis due to intussusception of an endometrioma has been reported [282].

Grossly, endometrial implants may be described as bluish-gray nodules resembling "powder burns" ranging from 2 mm to 2 cm in diameter [277]. Adhesions and mural cysts surrounded by dense fibrosis may be noted in the area surrounding implantation [283]. Histologically, aggregates of secretory glands lined by cuboidal endometrial epithelial cells and embedded in endometrial stroma with surrounding fibrosis are seen. These glands can be cystic or filled with blood. The mucosa of the intestine is rarely involved but can demonstrate changes more often found with IBD, such as crypt architecture distortion and branching lymphoplasmacytic infiltration, and Paneth cell metaplasia [283], confined to the mucosa adjacent to the invading endometrial nodules. Uncommon features include mucosal ulcers, and polypoid masses [287]. Endometrial tissue is typically deep within the intestinal wall and it may not be present in endoscopic biopsies.

The classic clinical presentation is partial obstruction of the colon in an infertile woman of reproductive age with dysmenorrhea and dyspareunia. On pelvic examination there may be palpable nodules in the rectovaginal septum. Barium enema and CT scanning are usually nondiagnostic, but may demonstrate strictures, compression, obstruction, or polypoid masses of the intestine. However, the lesions of intestinal endometriosis are typically too small to exclude malignancy based on these imaging studies. Endoscopic evaluation may be normal in the presence of noninvasive serosal implants. If hematochezia is present, invasion of the mucosa by endometrial implants may be noted on endoscopy or, in the presence of obstruction, strictures or extrinsic compression of the lumen may be noted. Endorectal ultrasonography may be helpful in detecting intestinal wall invasion by endometrial implants [288]. Diagnosis is confirmed by laparoscopy or

laparotomy, with biopsy demonstrating the histological findings of endometriosis.

The differential diagnosis includes irritable bowel syndrome, IBD, intestinal ischemia, gastrointestinal or gynecological malignancy, and lymphoma.

Although medical therapies such as danazol and medroxyprogesterone are beneficial in the treatment of pelvic endometriosis, these compounds have not proved effective in the treatment of symptomatic intestinal endometriosis [289]. Laparoscopic carbon dioxide laser is used to ablate endometrial implants [290]. If the intestine is partially obstructed by an implant or fibrosis, segmental resection is recommended to exclude carcinoma [285].

Typhlitis

Typhlitis is an acute necrotizing inflammation of the colon, primarily involving the cecum, terminal ileum, and ascending colon, associated with chemotherapy-induced neutropenia. Also known as necrotizing enterocolitis, neutropenic enterocolitis, and ileocecal syndrome, it can also involve the small bowel, appendix, and other areas of the colon [179,291]. Typhlitis has also been noted in a number of immunosuppressed adult patients, such as those receiving chemotherapy for hematological and solid malignancies, transplantation patients, cyclic neutropenia, aplastic anemia, drug-induced granulocytopenia, and AIDS [179]. Typhlitis has been estimated to occur in 2.6%–33% of those at risk [179,292]. The incidence of typhlitis may be increasing with the increasing use of more aggressive chemotherapeutic and immunosuppressive regimens. Various types of chemotherapy may lead to typhlitis [293], and it occurs more commonly with induction chemotherapy than with consolidation chemotherapy. Patients classically present 10–14 days after initiation of chemotherapy with fever, diarrhea, and abdominal pain, which may localize to the right lower quadrant (60% of patients) in the presence of neutropenia [293,294]. Patients may also present with nonspecific findings of stomatitis, nausea, emesis, abdominal distention, and bloody stools. Rarely, signs of peritonitis and shock are present; however, perforation or sepsis should also be considered in the differential diagnosis of these patients. Occasionally, neutropenic patients will present with a septic picture but nonlocalizing signs or symptoms. Blood cultures may be positive in up to 50% of patients and usually grow enteric organisms, such as *Pseudomonas* spp., *Escherichia coli*, *Staphylococcus aureus*, *Clostridia* spp., and *Klebsiella* spp. [179]. Fungal organisms, such as *Candida* spp. and *Aspergillus* spp., were found in 14% of cases prior to death but in 53% of cases after death [179]. The pathogenesis of typhlitis remains unknown.

Typhlitis may be difficult to diagnose given the nonspecific signs, symptoms, and radiographic findings that accompany the disorder. The physical exam is typically unrevealing, although a boggy cecum may be palpable as a mass in the right lower quadrant [293]. Laboratory examination is most remarkable for severe neutropenia, usually with an absolute neutrophil count less than 500 [179]. Blood cultures may be positive for bacterial infection in 50%. Radiological investigation with plain films of the abdomen is rarely helpful but may demonstrate findings of dilated bowel, dilated cecum with a decrease in gas in the right lower quadrant, thumbprinting, or, in the case of perforation, free air. Barium enema is avoided because of the possibility of perforation. Ultrasound may demonstrate the nonspecific findings of a thickened bowel wall, intraabdominal abscess, and an enlarged cecum. Cartoni and colleagues demonstrated a 60% mortality in patients with a bowel wall thickness greater than 10 mm, compared with only 4% for patients with a bowel wall thickness of less than 10 mm [295]. Computed tomography scan is more sensitive than plain radiography and ultrasound for typhlitis, and may demonstrate findings of thickened bowel, thickened fascial planes, pneumatosis intestinalis, ascites, bowel distention, and mesenteric stranding [291]. Instillation of air by endoscopy may be hazardous and induce or worsen perforation.

Typhlitis must be considered in any neutropenic patient with fever, diarrhea, and abdominal pain. Appendicitis, diverticulitis, IBD, enteric infection, intussusception, intramural hemorrhage, leukemic infiltrate, and Ogilvie syndrome should all be considered in the neutropenic patient presenting with fever, diarrhea, and abdominal pain.

Survival depends on prompt recognition of this disorder, appropriate management, and return of the neutrophil count to normal. Both conservative medical therapy and more aggressive surgical management have been advocated but study results have been conflicting. Conservative management may be better for those patients with a more indolent course, whereas surgery is best reserved those with persistent abdominal pain, pneumatosis intestinalis, sepsis, and persistent small bowel obstruction. Medical therapy consists of bowel rest with nasogastric suction if necessary, intravenous hydration, and broad-spectrum antibiotics with *Pseudomonas* coverage. If the patient remains febrile after 72 h of antibiotics, antifungal therapy should be added and further investigations undertaken to rule out abscess or other complications. Granulocyte colony-stimulating factor (G-CSF) may be helpful in bringing about an increase in the neutrophil count of these patients, which typically leads to resolution of the colitis [296]. Close observation of patient clinical status and radiographic progression is necessary to determine if conservative management is successful. Surgery is indicated for clinical deterioration despite medical therapy, free intraabdominal perforation, persistent gastrointestinal bleeding after improvement of neutropenia, thrombocytopenia, and coagulopathy [292,293]. The preferred procedure is right hemicolectomy with ileostomy and stoma formation, because any anastomosis may break down in the presence of

neutropenia. Resection of all necrotic foci is imperative for the survival of the patient [292]. Mortality from typhlitis is high, ranging from 8% to 60% [294,295], whether treated medically or surgically. Patients who develop typhlitis during induction chemotherapy and are medically treated are prone to relapse during subsequent chemotherapy (up to 67%) [297].

Malacoplakia

This is a rare chronic granulomatous inflammatory disorder predominantly affecting the genitourinary tract (60%–75% of all cases) [298]. Involvement of the gastrointestinal tract ranks second in frequency, and the most common site of intestinal involvement is the rectosigmoid colon [298–300]. The average age of affected adults is 57 years, with an age range of 18–88 years. The majority of patients are asymptomatic although some patients have abdominal pain, diarrhea, hematochezia, malabsorption, weight loss, and occasionally fistulae or obstruction from an associated mass or stricture [298,300,301]. Nearly one-third of patients with gastrointestinal malacoplakia were found to have associated colorectal carcinoma [298,302]. Colonic malacoplakia associated with carcinoma is usually found adjacent to the tumor [299,303]. Malacoplakia is associated with a number of other conditions including chronic infection with coliform bacteria (especially *E. coli*) [304], chronic granulomatous processes such as sarcoidosis and tuberculosis [298], immunosuppressed states (HIV/AIDS, posttransplantation, hypogammaglobulinemia, during chemotherapy or treatment of IBD) [305,306], and malignancy.

Pathogenesis of malacoplakia is not well understood. The lesions of malacoplakia are soft plaques or polypoid lesions, measuring 1–20 mm or larger, yellow-tan to yellow-gray in color, usually elevated, at times with surrounding hyperemia and a central depression [302]. They can be single or multiple, segmental or diffuse, and can involve adjacent structures such as lymph nodes, mesentery, retroperitoneum, and bladder [307].

Physical examination findings may include abdominal pain, tenderness, abdominal mass, rectal tumor, or weight loss [301,308]. Diagnosis depends on the presence of classic histological findings of malacoplakia in a biopsy specimen or fine-needle aspirate (FNA) [309]. Because of the rarity of this condition, there is no accepted medical therapy.

Definition

Irritable bowel syndrome (IBS) is a functional bowel disorder in which abdominal pain or discomfort is associated with defecation or a change in bowel habit, and with features of abnormal defecation. This occurs in the absence of organic disease. No clear diagnostic markers exist for IBS so the diagnosis is based on clinical presentation. The diagnostic criteria have undergone three modifications since they were proposed in 1989. In 2006, the Rome criteria for the diagnosis of IBS were revised [1] and are summarized in Table 60.1. Supportive symptoms that are not part of the diagnostic criteria include abnormal stool frequency ([a] three or fewer bowel movements per week or [b] more than three bowel movements per day), abnormal stool form ([c] lumpy/hard stool or [d] loose/watery stool), [e] defecation straining, [f] urgency, or also a feeling of incomplete bowel movement, passing mucus, and bloating. Based on the predominant stool pattern, IBS can be subtyped clinically, as shown in Table 60.2, into:

- IBS with constipation (IBS-C)
- IBS with diarrhea (IBS-D)
- mixed IBS (IBS-M)
- unsubtyped IBS.

However, the validity and stability of such subtypes over time is unknown and is a subject of future research.

Societal impact of irritable bowel syndrome

Irritable bowel syndrome is the most prevalent digestive disease, accounting for 12% of visits to primary-care physicians and 28% of referrals to gastroenterologists [2]. It is the seventh most common outpatient diagnosis with a rate of 10.6 visits per thousand population per year [3]. Over 2 million prescriptions are written for IBS [4]. Although usually an outpatient disorder, IBS was the major discharge diagnosis in 96 000 inpatients as recently as 1976 [5]. As awareness of the disorder has increased and hospital admission criteria have become stricter, admissions for IBS have markedly decreased [6]. In a survey in the United States, the total prevalence of IBS was 14.1% although more than three-fourths of the patients were undiagnosed but fulfilled the IBS diagnostic criteria of Rome II [7]. Abdominal pain/discomfort was the most common symptom prompting consultation. Most sufferers also reported alternating constipation and diarrhea. The patients with IBS had more days off work (6.4 vs 3.0) and days in bed, reducing activities to a greater extent than nonsufferers. Health-care costs for the management of IBS are high. In a survey of health-service utilization, the odds of a patient with IBS incurring charges were 1.6-fold greater than for a similar asymptomatic individual, which translated into overall median yearly charges of $742 (in 1992 dollars) for each patient with IBS compared to $429 for controls [8].

Irritable bowel syndrome produces health consequences in addition to its economic costs. Outcome studies reported

greater impairments in health-related quality of life in patients with IBS than in the US general population [9,10]. In a recent health-related quality of life survey it was reported that patients with functional bowel disorder experienced functional limitations in social interactions, home management, and recreational activities, felt helpless, out of control, depressed and irritable, and perceived restrictions in lifestyle relating to toilet accessibility and eating [11]. In fact, IBS produces disability rates equal to or greater than severe organic gastrointestinal disease and is the second leading cause of absenteeism after the common cold, with patients with IBS missing three times as many workdays yearly as persons without IBS [12–14]. Doctor visits for IBS are associated with high medical costs. In a recent US study 49% of IBS patients sought medical care for abdominal symptoms [15]. Health-care seeking did not differ between males and females although the reasons for seeking medical attention differed by gender. Older age (55 years or older), fear of serious underlying disease, decreased bowel movements, dyspepsia, and pelvic pain were associated with seeking care in females. Among males, being disabled and abdominal cramping were the primary reasons for seeing a physician. Neither pain severity nor mental health status was associated with seeking care. The impact of IBS is emphasized by a British study reporting that 8% of patients with IBS retire early as a result of their symptoms [16].

Epidemiology of irritable bowel syndrome

Irritable bowel syndrome is a disorder of young people, with most new cases presenting before age 45 [17]. However, some reports suggest that the elderly are troubled by symptoms of IBS up to 92% as often as middle-aged persons [14,18–21]. Indeed, patients over 65 years old make 500 000 physician visits per year for IBS [22]. Many of the diagnoses of "painful diverticular disease" given to elderly patients may represent IBS [23]. Functional gastrointestinal disorders also are prevalent in pediatric populations. IBS symptoms are reported by 14% of high-school students and 6% of middle-school students in one study and in 16% of students aged 11–17 years in another [24–26]. Women are diagnosed with IBS two to three times as often as men (Fig. 60.1) [17,27,28]. Moreover, women make up 80% of the population with severe IBS [29]. Recent studies indicated that a history of abdominal pain or irregular bowel habits in first-degree relatives was significantly associated with IBS and dyspepsia [30]. Whether the familial associations may represent similar exposures in a shared environment, heightened familial awareness of gastrointestinal symptoms, or genetic factors is unclear. A recent study of monozygotic and dizygotic twins showed no difference in carewise concordanced rates between them (28% vs 27%) arguing against the importance of genetic factors in IBS [31]. Logistic regression analysis revealed that decreasing age and increasing psychosomatic score were independently associated with IBS. Multifactorial liability threshold modeling suggested that a combination of unique and shared environmental factors provided the best model for IBS. Fewer Asians and Hispanics appear to develop the syndrome relative to other ethnic groups [29,32]. The epidemiology of IBS outside the Western world is poorly characterized.

The number of patients with IBS seeking care is dwarfed by the number of individuals who experience symptoms of IBS. Using strict criteria, 9%–22% of the population experience symptoms diagnostic for IBS, yet only a small fraction of these (9%–33%) seek medical attention, suggesting that other factors are important in the decision to obtain medical care [18,19,33,34].

Clinical features of irritable bowel syndrome

Gastrointestinal symptoms of irritable bowel syndrome

Irritable bowel syndrome is a heterogeneous disorder with distinct symptom presentations. Different subsets of IBS can be defined based on the dominant symptom. (Table 60.2).

Abdominal pain

According to the new Rome criteria, abdominal pain or discomfort is a prerequisite clinical feature of IBS. The intensity

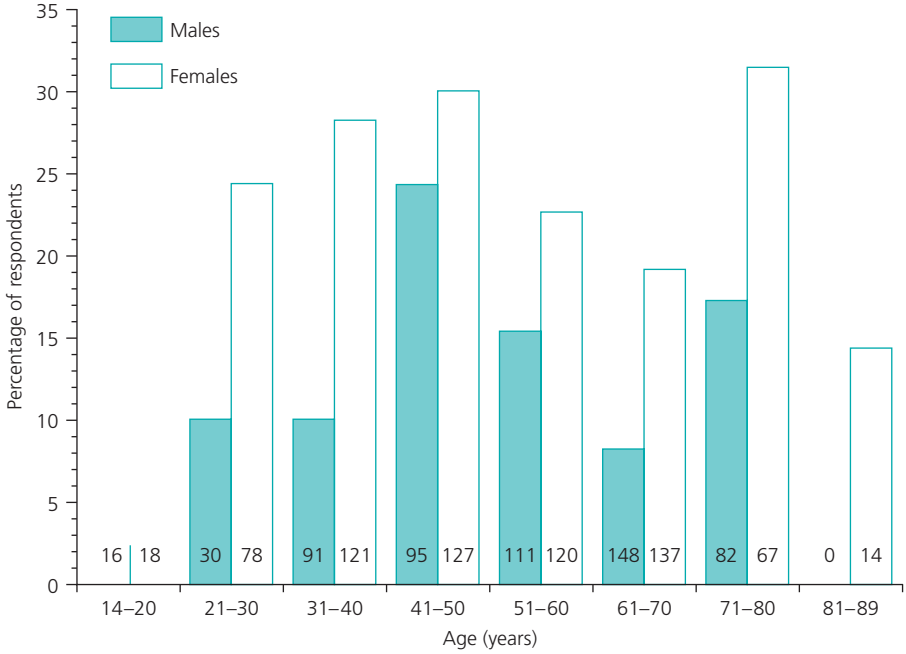

Figure 60.1 The age and gender distributions of individuals with symptoms of irritable bowel syndrome (IBS) are shown. The peak age range of symptom reports is in the 40s, although both younger and older persons experience symptoms. Women report IBS-like symptoms significantly more than men across all ages. From Longstreth & Wolde-Tsadik [29], with kind permission from Springer Science & Business Media.

and location of abdominal pain in IBS are highly variable, even within an individual patient. Abdominal pain in IBS is localized to the hypogastrium in 25%, the right side in 20%, to the left side in 20%, and the epigastrium in 10% of patients [35]. The pain is generally crampy or achy, although sharp, dull, gaslike, or nondescript pains are also common [36]. It is frequently relieved to some extent with defecation. Pain may be mild enough to be ignored or it may interfere with daily activities. Despite this, malnutrition as the result of inadequate caloric intake is exceedingly rare with IBS. Sleep deprivation is also unusual because abdominal pain is usually present only during waking hours. However, a recent study indicated that patients with severe IBS frequently wake repeatedly during the night and more than half of these patients reported that they were awakened by their abdominal pain [37]. Hence nocturnal pain is a poor discriminating factor between organic and functional bowel disease.

Several factors exacerbate or reduce pain in IBS. Many patients report increased symptoms during periods of stress or emotional turmoil as with job or marital difficulties. Defecation may provide temporary relief from the pain of IBS, whereas meal ingestion may exacerbate the discomfort usually 60–90 min postprandially. This is especially true after consuming foods rich in carbohydrates and fat [38]. In addition, female patients with IBS commonly report worsening symptoms during the premenstrual and menstrual phases [39]. Pain that is progressive, prevents sleep, leads to anorexia or inability to eat, or is associated with weight loss warrants exclusion of organic disease.

Alteration in bowel habits

Patients with IBS present with constipation (IBS-C), diarrhea (IBS-D), or constipation alternating with diarrhea (IBS-M) (Table 60.2). In some patients, the abnormality of stool consistency is not specific enough to meet criteria for subtyping (Unsubtyped). With constipation, stools are usually hard and may be scybalous or pellet-like. Long periods of straining may be required for fecal evacuation both in constipation- and diarrhea-predominant patients [40]. Constipation can persist for weeks to months, interrupted by brief periods of diarrhea. Feelings of incomplete fecal evacuation may lead to multiple attempts at stool passage daily. In diarrhea-prone patients, stools characteristically are loose and frequent but of normal daily volume. Generally, diarrheal stools occur only during waking hours, often early in the day, and an urgent desire to defecate after a meal is reported by 36% of patients [41]. Mucus discharge has been reported in up to 50% of patients with IBS [41]. As with abdominal pain, fecal urgency and loose stools may develop during stress. Early descriptions of IBS observed patient populations who presented with painless diarrhea, representing 17% in one report [36]. However, disorders such as lactase deficiency were less readily appreciated and others such as microscopic and collagenous colitis were undefined; it is conceivable many patients with functional diarrhea had one of these entities. In fact painless diarrhea does not strictly fulfill the current Rome criteria to be classified as IBS. A recent survey revealed that women with IBS report mucus discharge, a sensation of incomplete fecal evacuation, pellet-like stools, and distention more commonly than men [42]. It is important

to note that the symptoms of IBS typically wax and wane over time. Patients may have some days with symptoms and some days without. In a 12-week trial study of 59 patients with IBS, Hahn and colleagues [43] found that the population reported pain or discomfort on 50% of days. Bloating was reported on 33% of days and altered stool formation and passage were found in 25% and 18% of days respectively; 50% of the patients had at least one symptom for more than half of the study period. The symptoms lasted on average for 5 days or less although pain/discomfort and bloating tended to last the longest. It is not uncommon for patients with IBS to change their predominant bowel pattern from diarrhea to constipation or vice versa. Here the stability of each subtype over time is unknown. Symptoms that are not associated with IBS and that warrant exclusion of organic disease include nocturnal diarrhea, rectal bleeding, malabsorption, and weight loss.

Other gastrointestinal symptoms

Upper gut symptoms are common in IBS, with 25%–50% of patients reporting heartburn, early satiety, nausea, and vomiting; up to 87% note intermittent dyspepsia [44].

Evidence points to a significant overlap between IBS and gastroesophageal reflux disease (GERD). In a review of 15 studies published from 1966 through to January 2005, the weighted mean prevalence of GERD in patients diagnosed with IBS was 30.3%, whereas the mean prevalence of IBS in subjects with known GERD was 80.5% [45]. Based on the prevalence of IBS (12.1%) and GERD (19.4%) in the community, the rate of IBS in the non-GERD community was calculated to be only 5.1%. This suggests that IBS is relatively uncommon among patients without GERD.

It also appears that there is a great deal of overlap between dyspepsia and IBS. A community-based study in Spain reported that the prevalence of IBS was higher among subjects with dyspepsia (31.7%) than among those who reported no symptoms of dyspepsia (7.9%) [46]. Conversely among the subjects with IBS, 55.6% reported symptoms of dyspepsia. Other studies indicated that functional abdominal symptoms could change over time [47]. Those with predominant dyspepsia or IBS can fluctuate between the two. In contrast, those with predominant reflux symptoms seldom change to dyspepsia or IBS. It is conceivable that functional dyspepsia and IBS are two manifestations of a single, more extensive digestive system disorder. The symptoms of IBS are prevalent in patients with noncardiac chest pain, but not in patients with cardiac chest pain, suggesting overlap with other functional gut disorders [48].

Many IBS patients report the sensation of bloating as being the most bothersome symptom. This may be frequently accompanied by abdominal distention and increased gas production [49]. The relationship between bloating and actual distention manifest as an increase in abdominal girth is controversial. In a study of patients with IBS with diarrhea, with constipation, and with alternating bowel habits it was found that all patients irrespective of bowel habit reported greater bloating than controls, but only 48% showed distention as measured by abdominal inductance plethysmography [50]. Bloating correlated strongly only with distention in patients with IBS-C. Hence bloating and distention may differ pathophysiologically and this appears to be reflected in the bowel habit subtype.

A recent study indicated that the majority of patients with IBS have impaired transit and tolerance of intestinal gas loads [51]. The malfunctioning of colonic–intestinal or intestinal–intestinal reflex may contribute to gas retention and the symptoms of gas and bloating in patients with IBS. In contrast to healthy controls, rectal distention in patients with bloating failed to reduce lipid-induced gas retention [52]. Other patients with IBS may demonstrate a maximum rate of gas excretion greater than healthy subjects [53]. Although their total gas production was not increased, hydrogen production was higher. In these patients an exclusion diet reduced symptoms and produced a decrease in maximum gas excretion [53]. In a recent study it was demonstrated that the perception of intestinal gas accumulation depends on the mechanism of retention [54]. Obstructed evacuation increased symptom perception whereas gas retention in a hypotonic gut was virtually unperceived. Computed tomography has shown increased lateral profiles in patients with IBS, which was postulated to result from altered gastrointestinal motility or tone [55]. Another study has reported that those patients with significant bloating were most likely to have gained weight and more commonly had weak abdominal muscles [56]. This observation, however, was not confirmed by a subsequent study, which showed no anterior abdominal muscle weakness in patients with IBS with gas and bloating [57]. Hence the pathomechanism of bloating in IBS still remains undefined and is likely to be multifactorial.

Extraintestinal symptoms of irritable bowel syndrome

Although gastrointestinal symptoms predominate, extraintestinal complaints are common in IBS. Patients with functional gut disorders visit primary-care physicians three times as often for nongastrointestinal problems as do healthy persons and undergo more appendectomies and hysterectomies [27,58–60]. Chronic pelvic pain is much more commonly reported by IBS patients than patients with inflammatory bowel disease [61]. Genitourinary dysfunction, including dysmenorrhea, dyspareunia, impotence, urinary frequency, nocturia, and a sensation of incomplete bladder emptying, is prevalent [36]. Impaired sexual function is reported by 83% of patients with IBS compared with 30% of patients with inflammatory bowel disease and 16% of patients with peptic ulcers [62]. An association between IBS and primary fibromyalgia has been noted, with two-thirds of patients with IBS reporting rheumatological symptoms. Conversely, IBS

symptoms are found in 42% of patients with fibromyalgia [63]. Patients with both IBS and fibromyalgia have worse scores on health-related quality of life indices than patients with either disorder alone [64]. The presence of fibromyalgia in IBS patients seems to be associated with severity of bowel symptoms [65]. At the same time comorbidity with fibromyalgia results in somatic hyperalgesia in IBS patients [66]. Similarly, 63% of patients with chronic fatigue syndrome report symptoms of IBS [67]. Patients with functional bowel disorders have higher incidences of peptic ulcer disease, hypertension, low back pain, headaches, and rashes than the general population and more commonly report fatigue, loss of concentration, insomnia, palpitations, and unpleasant tastes in the mouth [35,68,69].

Pathophysiology of irritable bowel syndrome

The pathogenesis of IBS is poorly understood, although roles for abnormal gut motor and sensory activity, central neural dysfunction, psychological disturbances, stress, lumenal factors, and colonic microflora have been proposed. Unfortunately, there is no single pathophysiological abnormality that clearly separates IBS from organic gastrointestinal disease or from normality.

Gastrointestinal motor abnormalities in irritable bowel syndrome

Role of abnormal colonic motor activity

The myoelectrical activity of the colon is comprised of slow waves, which regulate the frequencies of some phasic contractions, and spike potentials, which elevate the membrane potential above a contractile threshold [70]. Spike potentials may occur in the form of short-spike bursts (SSB) of 5–15 s duration, which are temporally in phase with the slow-wave activity. Long-spike bursts (LSB) of 15–60 s duration are unrelated to the slow wave [28,71,72]. The SSBs are responsible for the generation of short-duration contractions, which are nonpropagative and segmenting in character leading to fecal mixing and resistance to stool passage [70]. The LSBs produce long-duration contractions, some of which are nonpropagative and some of which may propel feces in either an oral or aboral direction. Finally, high-amplitude propagated contractions are intensely propulsive, beginning in the right colon and occurring once or twice daily, and produce mass movements of feces and defecation [70].

Studies of colonic myoelectrical and motor activity under unstimulated conditions have not shown consistent abnormalities in IBS. A predominant slow-wave frequency of three cycles per minute (c.p.m.) with increased 3 c.p.m. motor activity was observed in both patients with diarrhea-predominant and constipation-predominant IBS in an older study that has not been confirmed by more recent studies [73,74]. Furthermore, similar slow-wave abnormalities are demonstrable in psychoneurotic patients without bowel symptoms, suggesting that the myoelectric disturbance is neither diagnostic for IBS nor pathogenic of symptoms [75]. Constipation-predominant patients were reported to exhibit increased numbers of SSBs whereas diarrhea-prone patients had reduced SSB activity [71]. Most investigators have observed no colonic motor abnormalities under basal conditions although others have reported increases in basal motility [73–77]. Increased numbers of high-amplitude propagated contractions have been noted in patients with diarrhea-predominant IBS compared to healthy volunteers [78]. Using scintigraphic assessment of colonic transit, selective acceleration in right colon transit has been shown in some patients with IBS-D [79]. It is unknown if these are pathogenic motor abnormalities in IBS or if all patients with diarrhea exhibit these findings. Similar studies have not been reported in constipation-predominant IBS, although patients with idiopathic constipation exhibit delayed right colon transit [80]. Recent dual barostat studies showed that there was attenuation of the colorectal tonic reflex in female patients with IBS-D [81]. These patients displayed significantly less than normal increase in rectal tone in response to colonic distention under fasting and postprandial conditions. How this abnormality contributes to the symptoms of IBS-D is unclear.

In contrast to the unstimulated colon, colonic motor abnormalities are more prominent under stimulated conditions in IBS. In normal volunteers, meal ingestion induces a rapid increase in spike potential and contractile activity that peak 20–30 min after eating, decrease to a basal level after 50–60 min, and may exhibit a second increase at 80 min [71]. Conversely, patients with IBS may exhibit increased rectosigmoid motor activity for up to 3 h after eating [72,82]. Although this response is most prominent in diarrhea-prone patients, patients with IBS-C also show an exaggerated gastrocolonic response albeit to a lesser degree [83]. In contrast to healthy volunteers, sham feeding increases rectosigmoid motility in IBS that is suggestive of a cephalic phase of the gastrocolonic response in affected patients [84–86]. Provocative stimuli induce exaggerated colonic motor responses in patients with IBS compared to healthy volunteers. Inflation of rectal balloons both in patients with diarrhea-predominant and constipation-predominant IBS leads to marked distention-evoked contractile activity that may be prolonged [72,87]. Patients with painful IBS exhibit greater increases in rectosigmoid motility after cholinergic stimulation than patients with painless diarrhea [88]. Intravenous cholecystokinin induces painful rectosigmoid contractions that reproduce the presenting symptoms in patients with IBS with postprandial pain [89]. An exaggerated motor response is demonstrable in patients with IBS after colonic perfusion of deoxycholic acid [90]. In contrast, it has been reported that rectal motor characteristics in response to isobaric distentions were not different between patients with constipation-predominant IBS,

patients with slow transit constipation, and healthy controls [91]. On the other hand, sensations of urge were reduced in slow transit constipation and sensations of pain were increased in IBS.

Until recently most of the colonic motility studies in IBS were performed in the rectosigmoid colon. Recording from the transverse, descending, and sigmoid colon, Chey and colleagues [92] reported that the motility index and peak amplitude of high-amplitude propagating contractions in diarrhea-prone patients with IBS were greatly increased compared to healthy subjects. These were associated with rapid colonic transit and accompanied by abdominal pain. Similar findings were made by another group who reported increased numbers of high-amplitude propagated contractions and reduced duration of increased colonic tone postprandially in diarrhea-prone patients with IBS [93].

Role of abnormal small bowel motor activity

Small intestinal motor patterns under unstimulated conditions are organized and well characterized. During fasting, the migrating motor complex (MMC) cycles every 90–120 min to clear the proximal gut of undigested debris. Prolonged manometric studies suggest subtle abnormalities in fasting small intestinal motility in IBS. Decreases in MMC contractile amplitudes in patients with constipation-predominant IBS and reductions in MMC cycle length in diarrhea-predominant individuals have been characterized, although these abnormalities have not been universally described [94,95]. These findings have not been observed during sleep [94–96]. Studies involving nonlinear analysis of 24-h jejunal motility revealed that patients with IBS had increased irregularities for the intercontractile intervals during phase II of MMC [97]. Other physiological motor patterns include discrete clustered contractions (DCC), which are bursts of phasic contractions occurring every minute in the duodenum or jejunum, and prolonged propagated contractions (PPC), which are intense ileal complexes that evacuate the ileum and prevent coloileal reflux. In patients with IBS, DCCs and PPCs have been reported to make up a larger fraction of fasting recording time; however, this has not been confirmed by recent investigations [40,98–101]. It is unlikely that these complexes have pathogenic significance because their occurrences are similar in patients with constipation and with diarrhea.

As in the colon, small intestinal motor abnormalities under stimulated conditions have been described in IBS. The fed motor pattern is a period of intense irregular phasic contractions that occurs for 2–3 h after eating. In both constipation-predominant and diarrhea-predominant IBS, the duration of the fed pattern is shorter than in healthy volunteers [40]. Increases in the postprandial intestinal contraction frequency have been observed in diarrhea-predominant and constipation-predominant IBS [101], although the contractile amplitudes were lower in constipation-predominant patients [102]. Recent studies [103] further demonstrated that increased frequency of retrograde propagation of duodenal pressure waves occurred postprandially in both constipation-prone and diarrhea-prone patients with IBS. This abnormal propagation pattern of duodenal pressure waves was associated with symptoms in this group of patients. Intravenous cholecystokinin evokes exaggerated high-amplitude ileal contractions in diarrhea-predominant IBS patients, whereas the anticholinesterase neostigmine induces frequent DCCs in both diarrhea-prone and constipation-prone patients [104]. Small intestinal transit of a meal is reportedly delayed in patients with IBS with constipation or distention plus abdominal pain whereas transit is characteristically accelerated in diarrhea-predominant patients [23]. Ileocecal function in IBS is variable with one study demonstrating delayed ileal emptying and decreased ileocecal clearance compared to healthy individuals and a second study reporting accelerated ileocecal transit both in constipation- and diarrhea-predominant patients [105,106].

Other motor abnormalities in irritable bowel syndrome

In addition to colonic and small intestinal motility disturbances, IBS is associated with motor abnormalities in other smooth muscle sites. Decreases in lower esophageal sphincter pressures and abnormalities of esophageal peristalsis have been found in IBS including increased spontaneous motor activity, repetitive contractions, and simultaneous waves in the esophageal body [72,107]. In contrast, the upper esophageal sphincter, which is striated muscle, exhibits no manometric abnormalities in IBS. Gastric slow-wave dysrhythmias (tachygastria, bradygastria) have been reported in dyspeptic patients with IBS symptoms [72]. Fasting gallbladder volumes and residual volumes after contraction are greater in patients with IBS, whereas gallbladder emptying is impaired, although there is no increase in gallbladder disease with IBS [108,109]. However, another study has reported that constipation-predominant patients exhibit enhanced gallbladder contraction, whereas patients with diarrhea exhibit impaired contraction compared to controls [110]. Sphincter of Oddi dysfunction has been described in association with IBS with a demonstration of impairment of the sphincter relaxation in response to exogenous cholecystokinin [111]. Detrusor instability of the bladder has been demonstrated in 10 of 30 patients with IBS compared to 1 of 10 controls [112]. Similarly, patients with IBS exhibit hyperreactive airway function after administration of the smooth muscle stimulant methacholine [113].

Visceral sensory abnormalities in irritable bowel syndrome

A major current focus of investigation is to define the visceral sensory abnormalities that may be responsible for sensations of pain, gas, or bloating in IBS. Perception of abdominal symptoms is mediated by afferent neural pathways, which

are activated by visceral stimuli acting on chemoreceptors (which sense osmolarity, temperature, pH), mechanoreceptors (which are located in the gut wall and discharge in response to changes in tension), and receptors in the mesentery, which may play a role in painful stimulation of the gut [114]. Information from these activated receptors is carried in spinal afferent nerves, which synapse in the dorsal horn of the spinal cord. From there, the impulses are transmitted to the brain where conscious perception occurs. It is postulated that IBS results from sensitization of afferent pathways such that normal physiological gut stimuli not perceived by healthy individuals induce pain in the patient with IBS. The sensitizing event responsible for induction of symptoms in IBS is unknown.

Disturbed sensation under basal conditions

The temporal association of symptoms with gut myoelectric and motor events provides evidence for disturbed visceral sensation under unstimulated conditions. Myoelectric recordings show correlations between the appearance of intense, fused colonic SSB and abdominal pain in patients with constipation-predominant IBS [72]. Irregular jejunal motor activity has been described coincident with the development of abdominal pain although other investigators have detected no abnormal motor patterns [95,115,116]. In one study, 61% of PPCs were associated with symptoms in patients with IBS compared to 17% in controls [98]. Similarly, DCCs were correlated with abdominal pain reports in four of 12 patients with IBS but in no healthy volunteers [98] (Fig. 60.2). Another investigation has shown that nearly half of patients with IBS perceive different phases of the MMC as discomfort, a tugging sensation, or frank pain [40]. In contrast to healthy individuals, patients with IBS possess the ability to sense physiological motor events in the gastrointestinal tract.

These findings may provide an explanation for older studies postulating a role for intestinal gas in the generation of abdominal symptoms in patients with functional bowel disorders. It was once believed that affected patients had abnormal amounts or distributions of intestinal gas. Early investigators described an entity called the splenic flexure syndrome, which consisted of severe left upper quadrant abdominal pain associated with apparent gas collections in the splenic flexure on abdominal radiographs [117]. Relief could be obtained by defecation, passage of flatus, or administration of an enema, and symptoms were reproducible by inflation of a balloon in the splenic flexure. Subsequent studies have shown that the absolute volume of gas in patients who complain of gas and bloating is normal. Using a washout technique, total volumes and transit times of intestinal gas were similar in asymptomatic individuals and in subjects complaining of excess gas [49]. However, patients with complaints of excess gas refluxed more gas from the intestine to the stomach and complained of distention and pain at low volumes of gas infusion that did not affect the controls. In addition to showing abnormal propulsion of intestinal gas, abnormal sensitivity to physiological amounts of intestinal gas is also demonstrable in patients with functional symptoms. Recent studies reported that in a subgroup of patients with IBS who were low hydrogen producers, lactulose ingestion lowered sensitivity thresholds for perception of bloating even though breath hydrogen excretion and mouth-to-cecum transit were similar to healthy controls [118]. It is conceivable that this group of patients might have hypersensitivity to products of colonic fermentation.

Disturbed sensation under stimulated conditions

As with studies of motor activity, patients with IBS frequently exhibit exaggerated sensory responses to visceral stimulation. Postprandial symptoms in IBS are associated with characteristic motor patterns. Postprandial pain has been temporally related to entry of the food bolus into the cecum in 74% of patients [23]. Some patients with concurrent

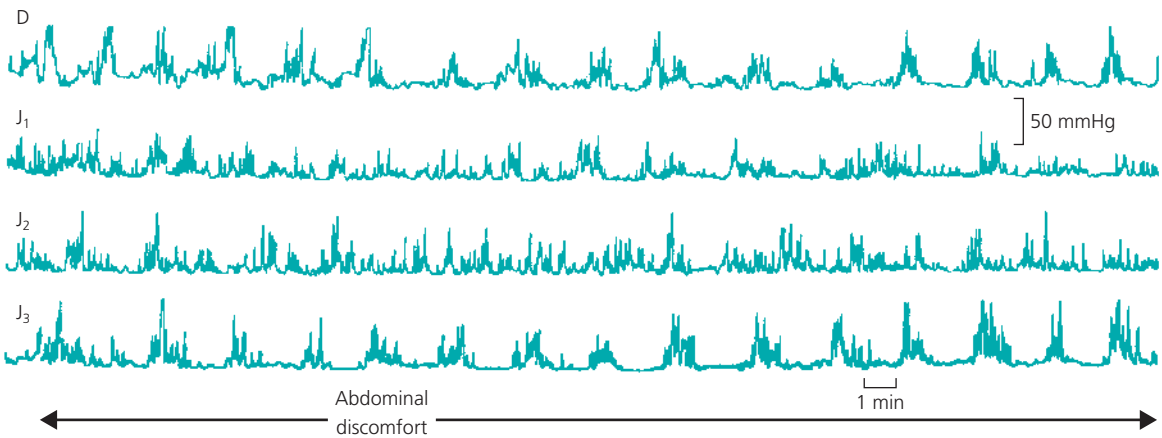

Figure 60.2 A manometric recording of small intestinal motility from a patient with irritable bowel syndrome (IBS) shows 30 min of discrete clustered contractions in the duodenum and jejunum which are associated with discomfort. nonulcer dyspepsia and IBS experience postprandial pain in association with increased rectosigmoid pressure [119]. Similarly, food has been shown to induce intestinal bursts that correlate temporally with pain [90]. A human clinical study showed that lipids lowered the thresholds for the first sensation of gas, discomfort, and pain in patients with IBS [97]. Furthermore, patients with IBS had an increased area of referred pain after lipid intake that was not observed in healthy subjects. The lowered threshold of discomfort evoked by intraduodenal lipid fusion was observed in both IBS-D and IBS-C patients whose major symptoms were rectal urgency and abdominal pain respectively [120]. These symptoms were reproduced during intraduodenal lipid infusions, suggesting that lipids may be responsible for postprandial symptom exacerbation in IBS. The rectal sensitivity to intraduodenal lipid was nutrient-specific as it was not observed with carbohydrates infusion [121]. This abnormal response was largely unaffected by psychological factors, sex or predominant bowel habit [122].

Exaggerated symptoms can be induced by visceral distention in patients with IBS. Rectal balloon inflation produced nonpainful and painful sensations at lower volumes in patients with IBS than in healthy controls without altering rectal tension, which was suggestive of visceral afferent dysfunction in IBS [123] (Fig. 60.3). This effect persisted even after the exclusion of psychological factors such as neuroticism. However, more recent studies suggested that psychological factors influenced pain thresholds in patients with IBS as stress altered sensory thresholds [102,103]. When perception tests that minimize psychological influences were used, many patients with IBS showed a normal sensory threshold. In fact, there are studies suggesting that the increased colonic sensitivity in IBS was strongly influenced by a psychological tendency to report pain and urge rather than actual increased rectal sensitivity [124]. On the other hand, sexual abuse was not associated with a lower pain threshold in patients with IBS. The visceral hyperalgesia of IBS appears to be selective for mechanoreceptor-activated stimuli as perception of intestinal mucosal electrical stimulation is normal in IBS [125]. In patients with IBS visceral hypersensitivity is not limited to the colon and rectum. Enhanced sensitivity to distention of the small bowel has been demonstrated. Jejunal sensitivity is increased after feeding in patients with IBS [126]. Furthermore, nonperceived rectal stimulation appears to modify the intensity of jejunal perception to a greater extent in patients with IBS than in healthy controls. Similar studies showed gastric and esophageal hypersensitivity in patients with nonulcer dyspepsia and noncardiac chest pain, respectively [123,127]. Furthermore, patients with IBS, nonulcer dyspepsia, or both all exhibited similar hypersensitivity to small intestinal distention, raising the possibility that these conditions have a similar pathophysiological basis [128]. Other studies of patients with IBS and nonulcer dyspepsia report enhanced sensitivity to esophageal distention, which is suggestive of a generalized visceral hyperalgesia in the functional bowel disorders [129,130]. One group has categorized patients with IBS into three groups based on the response to rectal distention [131], including:

- those with a sensitive rectum, with a low sensory threshold to distention, and normal to low intrarectal pressures
- those with a stiff rectum, with normal to low sensory thresholds, and high pressures
- those with an insensitive rectum, with a high sensory threshold, and normal or high pressures.

It should be noted that the sensitive rectum subtype was found in 57% of diarrhea-predominant patients compared with only 7% of patients with constipation. Seventy-five percent of diarrhea-predominant patients exhibited abnormal balloon distention responses compared with 30% of patients with constipation, suggesting that visceral hypersensitivity is not universal in IBS. This has been questioned in a study involving both rectal and sigmoid distention in patients with IBS [132]. In an investigation of patients with IBS with normal perception of rectal distention, all of them exhibited abnormal responses to sigmoid distention including alterations in colonic compliance and reflex relaxation. The duration of symptoms does not seem to be a factor in the degree of visceral hypersensitivity [133]. Finally, some investigators have postulated that IBS symptoms may result from interaction of visceral sensory dysfunction and abnormal gut motor patterns. In a study of women with IBS, those who exhibited enhanced perception of small intestinal distention had abnormal postprandial intestinal motor patterns [134].

The relationship between symptoms of IBS and hypersensitivity to rectal distention was examined in a recent study [135]. The proportions of IBS-D, IBS-C, and the alternating type were similar in hypersensitive and normosensitive

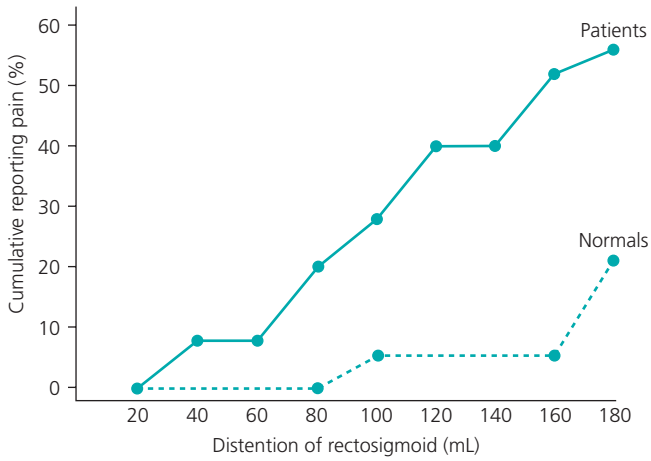

Figure 60.3 Perception of rectal balloon inflation is compared in healthy volunteers (dashed line) and patients with irritable bowel syndrome (IBS) (solid line). More patients with IBS reported pain with rectal distention. Furthermore, they experienced pain at much lower volumes than the healthy volunteers. From Whitehead et al. [123], with kind permission from Springer Science & Business Media.

subgroups. No individual IBS symptom could accurately predict the presence of hypersensitivity. Hence selection based on clinical parameters is unlikely to discriminate individual patients with IBS with visceral hypersensitivity from those patients with normal visceral sensitivity reflecting the complexity of the pathogenesis of IBS.

In addition to visceral hyperalgesia, patients with IBS exhibit abnormal pain referral patterns with balloon inflation of the stomach, small intestine, or colon [70,136,137]. In contrast to healthy controls who perceive discomfort in only one quadrant with colonic distention, IBS patients experience pain diffusely in the right upper and lower quadrants, right flank, hypochondrium, and epigastrium as well as in the back, shoulders, thighs, and chest [136] (Fig. 60.4). One group has proposed that, when alterations in viscerosomatic referral patterns are coupled with hypersensitive perception of rectal distention, visceral sensory abnormalities can be detected in nearly all IBS patients and so represent objective markers for the disorder [138].

In contrast to enhanced gut sensitivity, patients with IBS do not exhibit heightened sensitivity elsewhere in the body. Patients with IBS and Crohn's disease exhibit higher touch and pain thresholds with electrical stimulation of the skin than normal volunteers [139]. Furthermore, patients with IBS, lactose intolerance, and healthy volunteers exhibit similar perceptions of ice water immersion of the hand [140]. The afferent pathway disturbances in IBS therefore appear to be selective for visceral innervation with sparing of somatic pathways.

Visceral and somatic sensitivity disturbances were investigated in patients with IBS and fibromyalgia [141]. Patients with IBS and with IBS with fibromyalgia demonstrated rectal hypersensitivity in comparison to controls whereas patients with fibromyalgia tolerated rectal distention without discomfort. On the other hand, patients with fibromyalgia with or without IBS demonstrated somatic hypersensitivity involving all layers of the bodywall (skin, subcutis and muscle). These observations suggest that although IBS and fibromyalgia share a common hypersensitivity background, other mechanisms may modulate perceptual somatic and visceral responses in these two groups of patients.

Central nervous system factors in the pathogenesis of irritable bowel syndrome

The role of central nervous system factors in the pathogenesis of IBS is strongly suggested by the clinical association of emotional disorders and stress with symptom exacerbation and the therapeutic response to therapies that act on cerebral cortical sites.

Central neural dysfunction in irritable bowel syndrome

It is not known whether IBS represents a primary gut disturbance with inappropriate input from the central nervous system or a central nervous system disorder with centrally directed changes in gut motor and sensory activity [142]. It is further undefined if the peripheral afferent nerve pathways that project from the gut to the brain exhibit abnormalities. New technologies are being developed to study this issue. Using cerebral evoked potential recordings, investigators reported that afferent pathways stimulated by esophageal distention are not abnormal in noncardiac chest pain and concluded that perceptual disturbances result from abnormalities in the central nervous system [143]. Conversely, evoked potential recordings in patients with nonulcer dyspepsia and with IBS show abnormal waveform latencies and amplitudes suggestive of visceral afferent dysfunction [144,145]. The presence of peripheral afferent dysfunction in IBS is uncertain. Recent studies indicated that visceral hypersensitivity in IBS appears to be related to alterations in the

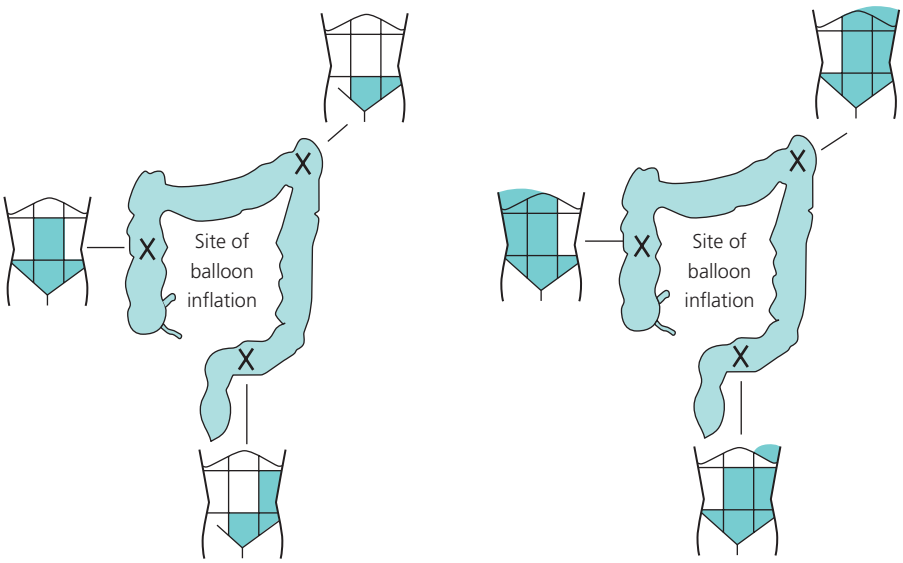

Figure 60.4 Pain referral patterns on inflation of colonic balloons is compared in healthy volunteers **(left)** and patients with irritable bowel syndrome (IBS) **(right)**. Colonic distention in healthy volunteers produced discomfort generally localized to a single abdominal quadrant whereas inflation in patients with IBS produced diffuse abdominal pain, providing evidence for altered viscerosomatic pain referral in IBS. nervous system rather than to biochemical parameters such as the tension and strain of the gut wall [146].

Cerebral functioning in IBS is poorly understood; however, methodologies to assess neurological disease are being used to address this issue. Both mental stress and administration of the cholinesterase inhibitor neostigmine evoke increases in colonic motility and changes in electroencephalographic waveforms, which are exaggerated in patients with IBS compared to healthy volunteers, suggesting that both the gut and brain are hypersensitive in IBS [147]. Functional brain imaging using positron emission tomography (PET) and functional MRI (fMRI), based respectively on regional blood flow or degree of oxygenation, demonstrated differences in central pain modulatory systems between IBS patients and healthy controls. These studies showed that visceral stimulation such as rectal distention activated corticolimbic modulatory systems including the insular cortex, thalamus and hypothalamus, right ventrolateral prefrontal cortex, amygdale, and anterior cingulated cortex (ACC). Many of these brain regions are associated with unpleasant affect and autonomic responses [148]. Among these, the ACC is the region of particular interest with regard to pain regulation, stress response, and IBS. It consists of several structurally and functionally heterogeneous regions as shown in Fig. 60.5. This area processes information on stimulus intensity, emotion, mood, and attention, and is also the area involved with unpleasant affect and autonomic responses. The ACC consists of two subregions (Fig. 60.5):

- an anterior perigenual ACC (pACC)
- a more dorsal and caudal portion located in the middle of the cingulated gyrus, the mid-cingulated cortex (MCC).

With painful visceral stimulation, there is an increase in activity of the pACC associated with emotional distress and an increase in activity of the MCC where pain is coupled with fear and with increased attention to the stimulus and inhibition of motor activity [149]. Despite inconsistencies across the studies, in general there is an association of ACC activation to rectal distention in IBS relative to controls [150]. Both fMRI and PET showed enhanced activities of unspecified areas of the ACC among patients with IBS [151]. Subsequent studies demonstrated more intense activation of the MCC [148,152–154] or pACC [155] in patients with IBS compared to controls, thus linking emotion or fear with visceral pain in these patients. This heightened pain sensitivity of the brain–gut axis may contribute to abnormal processing of sensory information in IBS resulting in visceral hypersensitivity.

Visceral hypersensitivity and abnormal brain activation in patients with IBS may occur as a result of enhanced sensitivity of visceral afferent pathways or abnormal cortical modulation related to cognitive or emotional factors. To draw a distinction between cognitive and non-cognitive processes, fMRI was performed in patients with IBS in response to rectal stimulation at distention pressure below conscious perception [156]. Patients with IBS showed a several fold higher activation at 10 mmHg, which remained at a similar higher level at 15 and 20 mmHg (all subliminal distention pressures), suggesting the presence of hypersensitivity of the neural circuitry in IBS irrespective of stimulus-related cognitive processes. This is in agreement with work from Verne and colleagues [157] who came to a similar conclusion based on the presence of increased activations in primary pain processing areas of the thalamus and insula in patients with IBS. Other groups, however, have suggested that differences in central pain modulation by emotional and cognitive factors may be responsible for some IBS-specific alterations in visceral perceptin and associated altered autonomic response [152,158]. In fact, a recent fMRI study showed that placebo

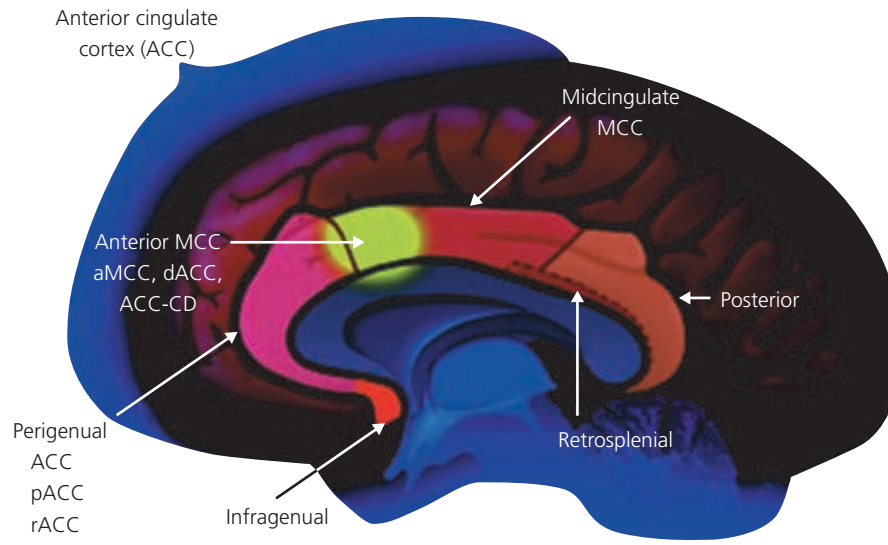

Figure 60.5 Structure of the cingulated cortex. The anterior region of the mid cingulated cortex (MCC, shown in green) is a subregion of the anterior cingulated cortex. Painful visceral stimulation caused an enhanced activation of this region in irritable bowel syndrome, which is coupled with fear and increased attention to the stimulus. analgesia was accompanied by large reductions in pain-related brain activity (thalamus, somatosensory cortices, insula, and anterior cingulated cortex) in patients with IBS [159].

Abnormal psychological features in irritable bowel syndrome

Abnormal psychiatric features are recorded in up to 80% of patients with IBS, especially in referral centers; however, no single psychiatric diagnosis predominates [17,123,160,161]. The lifetime incidences for major depression, somatization disorder, generalized anxiety disorder, panic disorder, and phobias are higher in patients with IBS than in healthy controls [162,163]. An early investigation observed that 80% of patients with IBS had underlying depression or anxiety, whereas another study reported hysteria or depression in 72% of patients with IBS compared to 18% in normal volunteers [36,161,164]. Conversely, when depressed patients are examined, 25% meet the criteria for IBS compared to 2.5% of nondepressed controls [165]. Similarly, IBS is found in 59% of dysthymic patients [166]. A significant overlap of panic disorder and IBS has been observed, with similar demographic and clinical characteristics [167]. In one study, 46% of patients with panic disorder met criteria for IBS vs 2.5% of controls [168]. Increases in neuroticism and decreases in extroversion are reported in IBS [164]. Additional abnormalities associated with IBS include hostility, hypochondriasis, and increased interpersonal sensitivity [123]. In an illness attitudes assessment, three abnormalities specific to IBS were bodily preoccupation, hypochondriacal beliefs, and disease phobia [169]. Psychiatric features predate or occur simultaneously with the onset of bowel symptoms in 67%–85% of patients, suggesting that it is not the symptoms of IBS that induce psychiatric disease [123,170–172].

An association between prior sexual or physical abuse and development of IBS has been reported [12,173]. Rates of severe lifetime sexual trauma, severe childhood sexual abuse, and any lifetime sexual victimization are significantly greater in patients with IBS than individuals with inflammatory bowel disease [174]. Forms of sexual abuse associated with IBS include verbal aggression, exhibitionism, sexual harassment, sexual touching, and rape [175]. Sexually traumatized patients experience significantly higher rates of lifetime development of depression, panic disorder, phobia, somatization, ethanol abuse, and sexual dysfunction. Furthermore, they exhibit higher rates of physician visits and more gastrointestinal and nongastrointestinal symptoms, and they undergo more surgeries [173]. Another study has reported histories of sexual abuse in 40% of patients with functional lower gastrointestinal disease both in tertiary referral centers and in private gastroenterology practices [176]. Prior sexual abuse is more common in constipated patients and is not prevalent in patients with functional upper gut symptoms. In a complementary study, patients with prior abuse were more likely to report symptoms of IBS than those without abuse histories [177]. From a pathophysiological standpoint, sexual abuse was not associated with lower pain threshold in IBS patients [178]. The prevalence of functional dyspepsia and IBS was examined in 70 females reporting domestic violence to the police [179]. Seventy-one percent of women who experienced domestic violence have functional dyspepsia (67%) or IBS (47%). In two-thirds of the cases, onset of gastrointestinal symptoms occurred simultaneously with the abuse or soon after the abuse began.

A recent prospective study examined whether development of abdominal pain and IBS occurs following gynecological surgery [180]. Among women undergoing gynecological surgery for nonpain indications, the development of IBS was not significantly greater than controls. Abdominal pain not related to IBS did develop in 17% of women in the surgical group, suggesting that surgery facilitated its development. Only psychosocial variables predicted pain development, suggesting that pain development is associated with central registration and amplification of the afferent signal by way of cognitive and emotional input.

Only a small fraction of individuals with symptoms of IBS present to a physician. Investigators have attempted to characterize differences between symptomatic individuals who seek medical attention and those who do not, known as nonreporters. Patients with IBS have been shown to exhibit more personality abnormalities and greater illness behavior than nonreporters [58]. Similarly, patients with IBS possess psychiatric disturbances greatly exceeding the general population; however, nonreporters are not different from asymptomatic individuals [170]. How a person responds to his or her symptoms determines whether he or she will present to a physician. Patients with IBS have histories of more frequent and serious childhood illnesses resulting in school absences and pediatrician visits and report that gifts were provided during childhood illness, suggesting that their expectations for illness behavior involve a reward [68,181].

Role of stress on visceral function in health and irritable bowel syndrome

The role of the central nervous system in modulating gastrointestinal function has intrigued researchers for decades. Early investigations of the effects of stress reinforce the importance of the brain–gut axis in the regulation of colonic activities. Painful somatic stimuli, such as ice water immersion of the hand or tightening of a circumferential band around the head, were shown to produce rectal spasm and mucosal engorgement [182]. Psychological stressors have been shown to have similar effects. One hoax involved telling a medical student during proctoscopy that a rectal cancer had been found, after which he was shown a piece of potato that he was told was a biopsy of the alleged malignancy [183]. As with the painful stimuli, the rectum exhibited intense contractions and mucosal reddening, which disappeared when the hoax was revealed. Similarly, in seven

constipated subjects and eight with diarrhea-prone IBS, changes in rectosigmoid motility were inducible with stressful interviews [184]. Hostile or aggressive reactions provoked increased motor activity, whereas passive reactions or dejection led to motor quiescence. Other stressors such as anger, ball sorting, and stimulus differentiation testing increase colonic motility or spike potential activity in patients with IBS and controls [76,77,185]. The central nervous system also modifies visceral perception that suppresses or enhances afferent impulses from the gastrointestinal tract [114]. Hypnosis reduces perception of rectal distention in patients with diarrhea-predominant IBS with a lesser effect in constipated patients [186]. The lack of effect of hypnotherapy on rectal compliance or motor activity is indicative of active suppression of visceral afferent function by central nervous system activity.

Stressful stimuli also induce physiological responses elsewhere in the gastrointestinal tract. Vertigo induced by cold caloric stimulation of the external ear delays gastric emptying and converts the fed motor pattern to fasting complexes [187]. Barium radiography of the small intestine performed on subjects during stressful interviews show segmentation, spasm, widening of the mucosal folds, and areas of distention [188,189]. Psychological stress, as with intense participation in a video game or driving in rush hour traffic, decreases cycling of the intestinal MMC in healthy volunteers [190]. The relative effects of stress on small intestinal motility in patients with IBS compared to healthy individuals are controversial. Using radiotelemetry capsules in the small intestine, long periods of mental stress induced motor abnormalities in 19 of 22 patients with IBS compared to one of 10 controls [116]. In seven patients, MMC cycling was eliminated and in 18 patients there were episodes of irregular motor activity lasting 1–6 h. However, another study showed equivalent suppression of MMC activity in patients with IBS and controls as well as inhibition, rather than induction, of DCCs in both subject groups, suggesting that the intestine in patients with IBS may not be more susceptible to stress than those of asymptomatic controls [191].

Current stressful events may exacerbate symptoms in a large subset of patients with IBS, although they are not likely to be the cause of the IBS. A strongly positive relationship was reported between daily stress and daily symptoms in women with IBS [192]. Disturbances of sleep have been correlated with symptom development in IBS, especially in the morning [193]. In addition to current stressors, a history of severe emotional upheaval in the distant past is often elicited on careful questioning. Loss of a parent, either through death or marital dissolution, has been reported to be an important stressor in one-third of patients [194–196]. A strong association between IBS and posttraumatic stress disorder was noted [197]. Furthermore, military veterans returning from the Gulf War presented with gastrointestinal complaints and exhibited similar visceral hyperalgesic properties to patients with IBS, suggesting that a subset of persons with Gulf War syndrome may in fact have IBS [198].

Other studies on the pathogenesis of irritable bowel syndrome

Induction of irritable bowel syndrome by gastrointestinal infection

A number of studies correlate development of IBS with a prior gastrointestinal infectious illness. In an investigation of 544 patients with confirmed bacterial gastroenteritis, one-fourth reported persistently abnormal bowel habits 6 months later [199]. Seven percent developed IBS with a 3.4-fold increased risk in women compared to men. A similar study of 75 patients with acute gastroenteritis requiring hospital admission recorded that 20 had persistent symptoms for more than 6 months compatible with a diagnosis of IBS [200]. Since these two earlier reports [199,200], several other studies have also identified IBS as a sequela of infectious gastroenteritis with reported prevalence ranging from 4% to 31% and relative risk from 2.5 to 11.9 [201–204]. A metaanalysis of eight studies showed a median prevalence of IBS to be 9.8% compared with 1.2% in the control group. The pooled odds ratio was 7.3 (95% confidence interval 4.7–11.1). Conversely Chaudhary and Truelove reported that about one-third of IBS patients experienced an acute "gastroenteritis-like" illness at the onset of their chronic IBS symptomatology [36]. The above-cited studies have shown that IBS following an enteric infection occurred more commonly in females, affected younger rather than older patients, and those who had a protracted acute diarrheal illness. Prior gastrointestinal morbidity and prolonged use of antibiotics are also risk factors for developing postinfectious IBS [202]. Psychometric assessment at the time of acute infection found that those who developed IBS had higher scores for anxiety, depression, somatization, and neuroticism compared to those who recovered. Increases in ileal mast cell density are reported in IBS, raising the possibility that subtle inflammation is pathogenic [205].

In addition to IBS, other functional gastrointestinal symptoms may occur after infectious gastroenteritis [203,204]. In a prospective study of dyspepsia and IBS after an outbreak of salmonella gastroenteritis [203], it was reported that at 1 year, the relative risk for development of dyspepsia was 5.2 and for IBS was 7.8. Prolonged abdominal pain and vomiting during acute gastroenteritis were positive predictors for dyspepsia.

The microbes involved in the initial infection were *Campylobacter* sp., *Salmonella* sp., and *Shigella* sp. [199,200,206]. Those patients with *Campylobacter* sp. infection who were toxin-positive were more likely to develop postinfectious irritable bowel syndrome [207]. Increased rectal mucosal enteroendocrine cells, T lymphocytes, and increased gut permeability were acute changes following campylobacter enteritis, which could persist for more than a year and may contribute to postinfectious IBS [208].

Postinfectious IBS has also been reported to occur after a food-borne outbreak of acute gastroenteritis attributed to the norovirus [209]. After a 3-month interval, 23.6% reported symptoms consistent with postinfectious IBS compared with 3.4% who remained well (odd ratio 6.9). After 6 months the prevalence of IBS was similar among exposed and nonexposed individuals. In multiple logistic regressions, vomiting during the acute illness independently predicted risk of postinfectious IBS at 3 months. Hence IBS is common after presumptive viral gastroenteritis but might be more transient than after bacterial dysentery.

Altered gut flora in irritable bowel syndrome

In a provocative study, Pimentel and colleagues [210] reported that of the 202 patients with IBS, 78% had small intestinal bacterial overgrowth diagnosed using the lactulose hydrogen breath test. Forty-eight percent of the subjects who had eradication of bacterial overgrowth experienced symptomatic improvement. The validity of this interesting finding has been challenged by a number of other studies. Walters and Vanner [211] found no significant difference in the incidence of abnormal lactulose hydrogen breath test between patients with IBS and healthy controls. Furthermore, using a ^{14}C-D-xylose test, a test with acknowledged greater specificity for bacterial overgrowth, the incidence of positive tests among patients with IBS was much lower compared to the lactulose hydrogen breath test. Using jejunal aspirate to diagnose small bowel bacterial overgrowth, no increased incidence of bacterial overgrowth was found in patients with IBS compared to control subjects [212]. Therefore it appears that the lactulose hydrogen breath test may not be a reliable method to detect small bowel bacterial overgrowth. There are no convincing data to support the proposal that small bowel bacterial overgrowth plays an important role in the pathogenesis of IBS.

Studies of germ-free and colonized animals have indicated that the microbiota influences the structure and function of the gastrointestinal tract. It appears that signaling from the enteric bacteria is required for mucosal homeostasis with regulatory effects not only on the epithelium and immune system but also on the enteric neuromuscular system [213]. This has led to the proposition that the gut microbiota may contribute to the onset and maintenance of IBS. A number of studies examined the composition and temporal stability of the fecal microbiota in patients with IBS and healthy controls [214–216]. Kessinen and colleagues found significant differences between the molecular profile of the fecal microbiota of patients with IBS compared with that of control subjects [216]. Several bacterial genera with *Lactobacillus* sequences appear to be absent from IBS and *Collinsella* sequences were greatly reduced in IBS. These intriguing results require confirmation. Furthermore, whether such changes are causal, consequential, or merely the results of constipation and diarrhea is unclear. In addition, the stability of the changes in the microbiota needs to be demonstrated.

Role of malabsorption or intolerance to specific foods

The role of carbohydrate malabsorption as a cause of bloating, pain, and diarrhea in IBS has been extensively evaluated. Lactase deficiency is a well-described syndrome where ingestion of milk products causes symptoms similar to those in IBS. Using hydrogen breath testing, 25.8% of one group of patients with presumed IBS exhibited lactase deficiency but 52% of these individuals did not relate their symptoms to lactose ingestion [205]. Another study of lactose-intolerant patients with IBS reported that symptoms were independent of lactase supplementation when given in a placebo-controlled fashion, suggesting that lactase deficiency was not pathogenic of IBS in these patients [217]. Conversely, a recent hydrogen breath test analysis of patients with presumed IBS identified a subset of patients with lactase deficiency unsuspected from their clinical history, who responded to dietary lactose exclusion [218]. This observation was confirmed in a more recent study [219], which reported that for the majority of patients with IBS with lactose malabsorption, which was previously clinically unrecognized, a lactose-restricted diet improved symptoms markedly both in the short term and the long term. These studies suggest that lactose malabsorption should be excluded before diagnosing IBS.

Malabsorption of other sugars has been proposed as a cause of symptoms in some patients with IBS. In one study, fructose and sorbitol, which are found in fruits as well as soft drinks and candy, produced prominent symptoms in most IBS subjects; however, dietary exclusion of these sugars was not performed [220]. A more recent investigation reported increased symptoms in patients with functional gastrointestinal disease after lactose or fructose plus sorbitol compared to healthy controls [221]. In this study, 40% of patients experienced symptom reduction after restriction of the offending carbohydrate. A recent study in Israel indicated that combined carbohydrate malabsorption was common in IBS and may contribute to symptomatology in many of the patients investigated [222]. However, the weight of available evidence suggests that carbohydrate malabsorption is not the cause of symptoms in most patients with IBS in the United States, although intolerance to certain sugars probably plays a role in some individuals.

Food hypersensitivity likely plays only a minor role in most patients, although some individuals with IBS may have a true allergic component to their symptoms [223]. In a study of 14 patients with diarrhea-predominant IBS who noted symptoms after eating wheat, dairy products, coffee, tea, or citrus fruits, a blinded challenge with the offending food led to worsening of the symptoms in six patients; this was associated with elevations in rectal prostaglandin E_2 [224]. Subsequent studies, however, have reported that only a small fraction of diarrhea-prone patients with IBS improve on an exclusion diet, an effect which may not be greater than

with placebo [225,226]. Even those individuals with positive skin test responses to particular foods do not show symptom resolution on dietary exclusion of those foods [227]. In a recent food hypersensitivity study, serum immunoglobulin G4 (IgG4) antibodies to common foods like wheat, beef, pork, and lamb were elevated in all patients with IBS including IBS-D, IBS-C and alternators [228]. No correlation was seen between the pattern of elevated IgG4 antibody titers and patients' symptoms and so the clinical significance of this observation is unclear. In another study comprising 25 patients with IBS, IgG4 antibodies to milk, eggs, wheat, beef, pork, and lamb were found to be commonly elevated. Foods with IgG4 titers greater than 250 μg/L were excluded for 6 months and this resulted in a significant improvement in pain severity and frequency, bloating severity, bowel habits, and effect of IBS on life in general [229]. However, this study did not include a control group and so a placebo effect cannot be ruled out.

Disturbed neurohumoral activity

Systemic disturbances in neural and hormonal activity have been explored as pathogenic factors in IBS. Efferent vagal dysfunction is suggested by demonstrations of reductions in vagally mediated increases in lower esophageal sphincter pressure after abdominal compression, impaired pulse variability with inspiration, and reduced ratios of insulin-induced peak gastric acid output to pentagastrin-stimulated maximal acid output in subsets of patients with IBS [230]. Decreases in digital temperatures and enhanced peripheral electromyographic activity have led investigators to postulate a diffuse autonomic neural disturbance in IBS [231]. A quantitative assessment of sympathetic adrenergic and cholinergic and cardiovagal cholinergic function revealed abnormalities in nine of 33 patients with IBS [232]. Abnormalities of the viscerosensory–cardiovascular reflex exist in some patients with IBS. Arterial baroreflex sensitivity was found to be significantly higher in patients with IBS at baseline and increased during mild rectal distention in both patients with IBS and healthy controls. This increase persisted in controls during intense stimulation, but baroreflex sensitivity returned to baseline in the patients with IBS, suggesting altered viscerosensory processing in the central nervous system [233]. Recent studies indicate that sex differences exist among patients with IBS in terms of alterations in autonomic function [234]. Decreased parasympathetic tone and increased sympathetic activity in response to sigmoid colon distention were prominent in male patients with IBS but not in female patients. This may be the result of gender differences in corticolimbic processing of visceral stimuli. Another investigation suggested that patients with constipation-predominant IBS exhibit abnormalities of cholinergic function whereas diarrhea-prone individuals have evidence of adrenergic neural dysfunction [235]. Parasympathetic tone was significantly lower in the constipation-predominant compared to the diarrhea-predominant patients [236]. Prolongation of rapid eye movement sleep with episodes of sleep apnea has been reported in IBS, raising the possibility that the central nervous system exhibits abnormalities outside the brain–gut axis [237,238]. Blunting of α-adrenergic pathways in the central nervous system is suggested by the observation of impaired growth hormone release in patients with IBS, but not in patients with ulcers or in healthy controls, in response to α_2-adrenergic receptor stimulation [239]. Furthermore, patients with IBS appear to have an exaggerated response to corticotropin-releasing hormone (CRH) [240]. Exogenous CRH not only induced higher plasma adrenocorticotropic hormone levels in patients with IBS, it also produced abdominal symptoms, which were accompanied by a greater motility index in the colon as well as duodenal dysmotility in this group of patients. Intravenous infusion of CRH induced rectal hypersensitivity to repetitive painful rectal distention, suggesting a potential role of CRH in the pathogenesis of visceral hypersensitivity in IBS [241]. Patents with IBS in which diarrhea is predominant showed a significant postprandial increase in cortisol that was not evident in healthy subjects or in patients with constipation-predominant IBS [242]. Hormonal disturbances have been postulated to be pathogenically important in patients with IBS who experience symptoms during menses [60,243]. Gut hormones exert a wide range of effects on gastrointestinal functions. Abnormal circulating pancreatic polypeptide, neurotensin, insulin, motilin, cholecystokinin, and gastrin levels are reported in some patients with IBS [244–247]. Patients with IBS maintained the cyclic variation of plasma motilin during the occurrence of interdisgestive migrating motor complex although the fasting and postprandial motilin levels were higher compared to those in healthy controls, independent of predominant bowel habits [248]. In women with IBS, higher urinary norepinephrine, epinephrine, and cortisol levels have been observed [249]. The roles of these neurohumoral disturbances in the pathogenesis of IBS are unclear but they are likely to be epiphenomenal.

Nitric oxide (NO)-containing neurons are found in abundance in the myenteric plexus. Although NO does not seem to play a major role in normal rectal sensation or tone in health, administration of nitro-L-arginine methyl ester (L-NAME), a specific NO synthase inhibitor, significantly increased the threshold for discomfort/pain in patients with IBS, suggesting that abnormal release or action of NO may contribute to visceral hypersensitivity in IBS [250].

Protease-activated receptor-2 is present in a variety of sensory neurons. They are proalgesic receptors and when activated, may contribute to visceral hypersensitivity. Trypsin and tryptase expression and release were increased in colonic biopsies from patients with IBS [251]. These biopsies released mediators that sensitized murine sensory neurons in culture. Sensitization was prevented by a serine protease inhibitor and was absent in neurons lacking functional protease-activated receptor-2 [251]. Furthermore, supernatants from

colonic biopsies of patients with IBS caused visceral hyperalgesia and allodynia in mice when administered in the colon. These studies demonstrated that proteases are released in IBS and they can directly stimulate sensory neurons and generate hypersensitivity symptoms through activation of protease-activated receptor-2.

Serotonin (5-HT) is present in abundance in the gastrointestinal tract. It may play an important role in the regulation of gastrointestinal motility and visceral perception. A clinical study indicated that 5-HT containing enterochromaffin cells in the colon were increased in patients with diarrhea-predominant IBS compared to healthy subjects or patients with ulcerative colitis [252]. Furthermore, postprandial 5-HT plasma levels were significantly higher in patients with diarrhea-predominant IBS compared to healthy controls [253]. These observations were confirmed in another study showing that patients with IBS-C with slow colonic transit had impaired postprandial 5-HT release whereas the patients with postinfectious IBS-D had higher peak levels of 5-HT and shorter colonic transit time [254]. Similar observations were made by Atkinson and colleagues [255], who further demonstrated that IBS-C was associated with a decreased 5-hydroxyindole acetic acid (5-H1AA) : 5-HT ratio whereas patients with IBS-D have normal plasma 5-H1AA concentrations but a reduced 5-H1AA : 5-HT ratio. These findings support the concept that patients with IBS-D may have reduced 5-HT uptake and that IBS-C may be associated with impaired release of 5-HT. Further in vitro metabolic studies using colonic biopsies from patients with IBS-C and IBS-D would help to clarify this issue. Overall, this group of studies suggests a possible role for 5-HT in the symptom generation of these patients and provides a rationale for the use of 5-HT agonists and antagonists in the treatment of IBS.

Immune activation and mucosal inflammation

Some patients with IBS, especially those with postinfectious IBS, display persistent signs of low-grade mucosal inflammation with activated lymphocytes, mast cells, and enhanced expression of proinflammatory cytokines [208]. These abnormalities may contribute to abnormal epithelial secretion and visceral hypersensitivity. In a recent study mast cells were found to be greatly increased in the terminal ileum, ascending colon, and rectum of patients with IBS-D and these patients showed visceral hypersensitivity in response to rectal distention [256]. Mucosal mast cells from patients with IBS secreted histamine and tryptase. These mediators markedly enhanced the firings of mesenteric nerves and stimulated mobilization of Ca^{2+} in dorsal root ganglia neurons [257]. The latter was inhibited by histamine H_1 receptor blockade and serine protease inactivation. Hence mucosal mast cells in patients with IBS may contribute to visceral hypersensitivity in this group of patients.

Abnormal immune activation occurs in some patients with IBS with augmental cellular immune responses and enhanced production of proinflammatory cytokines [258]. In a recent study, peripheral blood mononuclear cells from patients with IBS-D and with postinfectious IBS showed higher baseline interferon-α, interleukin-1β (IL-1β), and IL-6 levels and lipopolysaccharide-induced IL-6 secretion whereas colonic biopsy specimens did not reveal any inflammatory changes. These proinflammatory cytokines may alter mucosal barrier function. Interestingly, clinical studies have shown increased intestinal permeability in patients with IBS-D [259].

Psychological stress and anxiety can increase the release of proinflammatory cytokine [260]. This may contribute to dysregulation of the hypothalamic–pituitary–gut axis which has been reported to occur in patients with IBS [261]. Following intravenous infusion of CRH, an exaggerated release of both adrenocorticotrophic hormone and cortisol was observed in patients with IBS. This was accompanied by an increase of plasma levels of IL-6 and IL-8. Both IL-1β and tumor necrosis factor-α (TNF-α) synergistically stimulated the hypothalamo–pituitary–adrenal axis either directly or indirectly through activation of nociceptive, visceral, and somatosensory afferents [260]. Hence this series of observations provide a functional link between psychological stress, immune activation, and symptom generation in patients with IBS (Fig. 60.6).

Genetic indicators

Aggregation of IBS symptoms has been described in families, suggesting a possible contribution by genetic factors to the pathogenesis of this disorder. Studies on monozygotic and dizygotic twins, however, do not support a key role for genetic factors in IBS. The predominant influences appear to be environmental [31]. In recent years a number of biological molecules have emerged as potential genetic markers for IBS. These include molecules involved in serotonin metabolism [262], G protein translation of ligand receptor activation [263], and factors controlling production of pro- and antiinflammatory cytokines [264]. The *GN beta 3* gene regulates G protein translation of a majority of ligand–receptor activations and homozygous genotypes of the C825T polymorphism in the *GN beta 3* gene has been associated with functional dyspepsia [265] but not with IBS [263]. Imbalances in the genetically controlled pro- and antiinflammatory cytokine production may promote the low-grade mucosal inflammation observed in some patients with IBS. Studies by Van der Veek and colleagues [266] showed that the heterozygous (G/A) genotype that encodes for high secretion of the proinflammatory cytokine TNF-α was significantly more prevalent in the IBS group compared to controls (41% vs 26%), whereas the frequency of the A/A genotype that encodes low secretion of this cytokine was similar in both groups. However, the combination of the genotypes encoding low secretion for the counterinflammatory cytokine IL-10 (-1082 A/A) and high secretion of TNF-α (-308 A/A or G/A) was significantly more prevalent in the IBS group (9%) compared to controls (3%).

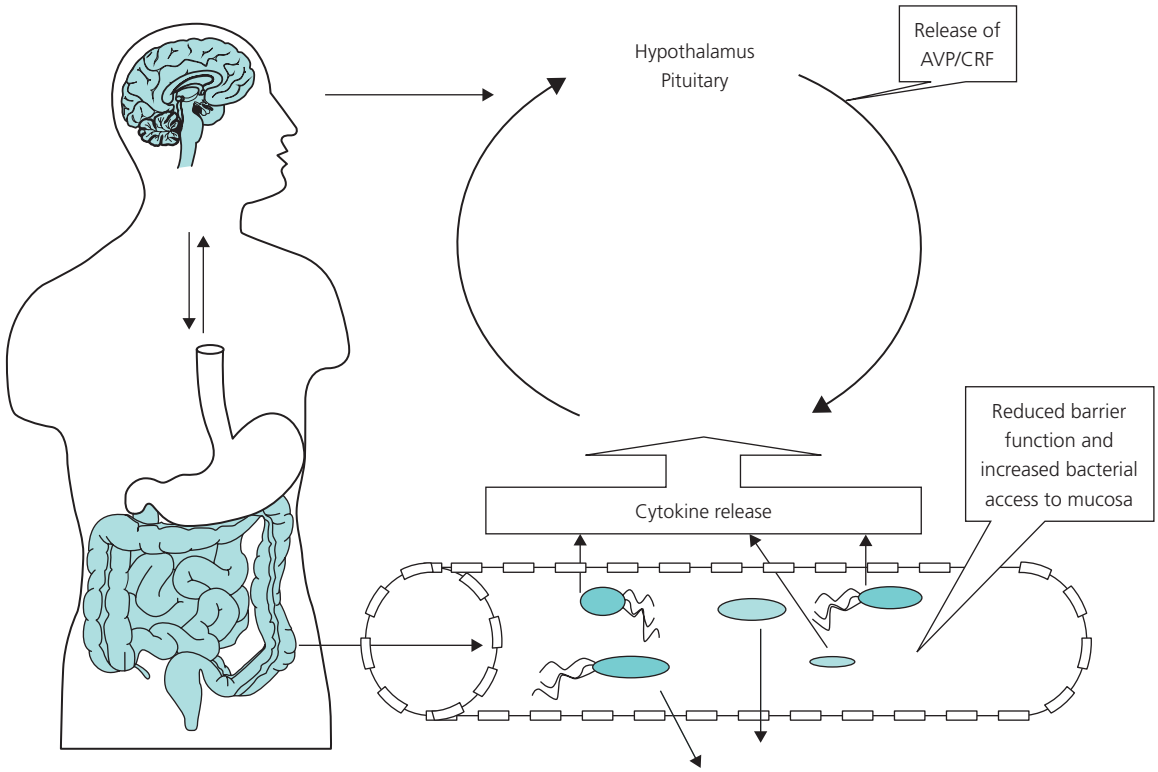

Figure 60.6 Functional link between psychological stress, immune activation, and irritable bowel syndrome (IBS) symptoms. Anxiety and stress induce an exaggerated release of corticotrophin-releasing hormone (CRH) in IBS. CRH infusion stimulates the secretion of proinflammatory cytokines, which may alter motor and secretory function and increase mucosal permeability. Cytokines such as interleukin-1β and tumor necrosis factor-α can synergistically activate the hypothalamo–pituitary–adrenal axis either directly or indirectly through stimulation of nociceptive, visceral, and somatosensory afferents. This positive feedback pathway provides a link between psychological stress, immune activation, and altered gut functions in IBS. From Shanahan [456], with permission from Elsevier.

Abnormalities in 5-HT metabolism have been implicated in the pathogenesis of IBS. Two proteins that influence the function of 5-HT and 5-HT receptors are serotonin transporter protein (SERT) or soluble carrier protein (SLC [6A4]) and p11 (S-180 A10, or calpactin I right chain). Camilleri and colleagues [262] found no difference in the messenger RNA for SERT compared with reference genes between any of the groups in the sigmoid or rectal mucosa. In contrast, they found a significant increase of p11 in the sigmoid mucosa, especially in those patients with IBS-C. Given that overexpression of p11 can increase serotonergic receptor functions (e.g., 5-HT_{1B} receptors) [267,268], it may influence the functions of the 5-HT pathways in the gastrointestinal tract. Furthermore, p11 increased surface expression of Nav 1.8 [269], $\text{TRVP}_{5\text{and}6}$ [270], and TASK-1 [271] in sensory nerves resulting in enhanced excitability of these ion channels, which may cause visceral hypersensitivity.

These new findings may provide new insight into the pathophysiology of the disorder and possibly suggest new targets for drug development. However, given that genetic polymorphisms are rather common and IBS is a heterogeneous group of disorders with very few components that are genetically determined, it is unlikely that genetic testing will help in the diagnosis of IBS.

Abnormal stool characteristics

Abnormal characteristics of the fecal material have been postulated as symptom inducers in IBS. As bile acids induce colonic contractions, investigators have proposed that patients with diarrhea-predominant IBS have bile acid malabsorption [71]. Although bile acid binders such as cholestyramine are used in IBS with anecdotal reports of success, this may be because of the general constipating effects of the resin. A recent study reported that about one-third of patients with IBS had bile acid malabsorption and 70% of these patients responded to bile acid sequestrants whereas only 15% responded to conventional therapy [272]. Others have proposed that elevated levels of fecal short-chain fatty acids may cause diarrhea in IBS; however, symptoms do not correlate with fecal levels of these compounds [273]. A clinical investigation revealed that diarrhea-prone patients have lower fecal concentrations of total short-chain fatty acids, acetate, and propionate, and higher levels of *n*-butyrate than controls [274]. The pathophysiological significance of these findings remains to be determined.

Diagnostic approach to the patient with presumed irritable bowel syndrome

History and physical examination in irritable bowel syndrome

Confident diagnosis of IBS relies on recognition of characteristic symptom profiles as well as the detection of alarm findings (weight loss, bleeding, fever, or palpable masses), which are more suggestive of organic disease. The symptoms that define IBS are prominent complaints of many other conditions including malignancies, inflammatory diseases, infections, and ischemic diseases of the gastrointestinal tract as well as some nongastrointestinal conditions. Several investigators have attempted to ascertain if specific symptom patterns can distinguish IBS from more severe illnesses. In a questionnaire survey, Manning and colleagues [275] defined four symptoms that were significantly more common in IBS than organic disease including relief of abdominal pain on defecation, looser stools with onset of pain, more frequent stools with the onset of pain, and abdominal distention. Ninety-one percent of patients with IBS had at least two of these symptoms compared with 30% of patients with organic disease. Other symptoms which were common but which did not distinguish IBS from organic disease included passage of mucus, a sensation of incomplete evacuation, fecal urgency, harder or less frequent stools at pain onset, pain eased by passage of flatus, and defecation before breakfast, at night, or between meals. In a study by Kruis and colleagues [276], an absence of organic disease was predicted by:

- the combination of pain, flatulence, and irregular defecation
- symptoms persisting for more than 2 years
- pain described as burning, cutting, strong, or terrible
- a defecation pattern of alternating defecation and constipation
- pencil-like or pellet-like stools
- the passage of mucus in the stools.

These initial investigations have been followed by international assemblies that have devised the commonly employed Rome I, and most recently Rome III, criteria [1,277].

More recent studies have quantified the reliability of symptom-based criteria in the diagnosis of IBS. An early evaluation observed that the Manning criteria could distinguish IBS from organic disease with a sensitivity of only 58% and a specificity of 74% [278]. Other investigators found that the Manning criteria were able to discriminate IBS from organic disease with a sensitivity and specificity of 90% and 87%, whereas the Kruis system exhibited a sensitivity of 81% and a specificity of 97%, respectively. When employed together, the two sets of criteria exhibited 80% sensitivity and 97% specificity for the diagnosis of IBS [279].

Clinical studies suggest that the positive predictive value of Rome II criteria for diagnosing IBS can be enhanced by excluding red flag symptoms suggestive of organic diseases [280]. The six red flags used by the studies were blood in stools, nocturnal symptoms, documented weight loss, antibiotic use, family history of colon cancer, and relevant abnormalities on physical examination. This recommendation was not supported by a subsequent study of 1434 patients with clinical diagnosis of IBS who completed questionnaires to identify Rome II criteria and red flag symptoms [281]. Red flag symptoms have modest but significant predictive value for identifying patients with functional gastrointestinal symptoms who are at risk for gastrointestinal cancers, IBD, or malabsorption. However, the fact that 84% of patients with functional gastrointestinal symptoms endorsed one or more red flag symptoms, significantly reduced the utility of these red flag symptoms as screening factors. The general consensus is that red flags may be useful for identifying patients who require additional diagnostic evaluation, but incorporating them into the Rome criteria would not improve sensitivity and would result in too many missed IBS diagnoses.

The physical examination of the IBS patient is usually normal. Abdominal compression may elicit tenderness, which is vague and poorly localized. Tender bowel loops are commonly palpable [27]. Masses, adenopathy, hepatosplenomegaly, ascites, blood in the stool, or autonomic or peripheral neuropathy are suggestive of organic disease and are not consistent with IBS.

Laboratory and structural findings in irritable bowel syndrome

A minimal laboratory and structural evaluation has been advocated as a screen for organic disease in the patient with presumed IBS. Basic testing includes a complete blood count to assess for anemia, leukocytosis, or leukopenia, a sedimentation rate to screen for inflammation, thyroid chemistries to exclude hormonal causes of altered bowel function, and serum electrolytes and stool studies for ova and parasites or *Giardia* antigen in patients with diarrhea. For diarrhea-predominant individuals, hydrogen breath testing to exclude lactose intolerance should be considered [282]. Empiric dietary lactose restriction is an alternative when breath testing is not available. For pain-predominant patients, plain abdominal radiography during an episode of pain can exclude intermittent bowel obstruction [282]. Sigmoidoscopy is recommended for most young individuals (< 50 years old) to rule out distal obstruction in patients with constipation and inflammatory diseases in those with diarrhea. In diarrhea-predominant patients, random biopsies are obtained to search for microscopic colitis. Sigmoidoscopy should reveal normal anatomy in IBS, although increased mucus secretion, mucosal engorgement, and pain with air insufflation are commonly noted [27]. In patients over 50 years of age, colonoscopy or air-contrast barium enema radiography are indicated because of the prevalence of colonic neoplasm in this age group. A recent technical review for practice guideline development by the American Gastroenterological

Association delineated factors to be considered when determining the aggressiveness of the diagnostic evaluation [282]. These include the duration of symptoms, the change in symptoms over time, the age and sex of the patient, the referral status of the patient, prior diagnostic studies, a family history of colorectal malignancy, and the degree of psychosocial dysfunction. A younger individual with mild symptoms would therefore require a minimal (or in select cases no) diagnostic evaluation whereas an older person or an individual with rapidly progressive symptoms should undergo a more thorough exclusion of organic disease.

The validity of this approach has been the subject of recent scrutiny. In the absence of alarm findings, a normal complete blood count and sedimentation rate provide 83% sensitivity and 97% specificity for the diagnosis of IBS [35]. However a study of 196 patients satisfying the Rome criteria I found no diagnostic yield from sedimentation rates, thyroid profiles, and stool examinations in the absence of specific historical or physical examination findings [20]. Furthermore, barium enema radiography or lower endoscopy revealed only one case with colon cancer, nine with polyps, and one with colitis out of a sample size of 196 patients [205]. In data from two other multicenter trials, lactose intolerance was diagnosed in 23% of patients, colonic structural abnormalities were found in 2%, abnormal thyroid chemistries were observed in 6%, and positive fecal ova and parasites were detected in 2% [283]. Nevertheless, a thorough initial evaluation of the patient with presumed IBS precludes the need for further diagnostic testing years later. In 112 patients with IBS followed for a median of 29 years, organic disease developed in only 10 patients a median of 15 years after the original diagnosis of IBS [284]. Some patients with diarrhea-predominant IBS may have undiagnosed celiac sprue. The symptoms of celiac sprue respond to a gluten-free diet so testing for celiac sprue in IBS may prevent years of morbidity and attendant expense. Decision analysis studies show that serology testing for celiac sprue in patients with diarrhea-predominant IBS has an acceptable cost when the prevalence of celiac sprue is above 1% and is the dominant strategy when the prevalence exceeds 8% [285]. In patients with concurrent symptoms of dyspepsia, upper gastrointestinal radiographs or esophagogastroduodenoscopy may be advisable. In patients with postprandial right upper quadrant pain, an ultrasonogram of the gallbladder should be obtained. Laboratory features that argue against IBS include evidence of anemia, elevated sedimentation rate, presence of leukocytes or blood in stool, and stool volume between 200 and 300 mL/day. These findings would necessitate other diagnostic considerations.

Treatment of irritable bowel syndrome

The treatment of IBS ranges from patient education and dietary modifications to medications or even psychological intervention. Some patients, especially those with new onset symptoms, will express relief that they do not have a serious condition such as cancer. Lifestyle modification with active patient participation may be helpful. In a randomized controlled trial involving 420 patients with IBS, it was reported that the introduction of a self-help guide book resulted in a 60% decrease in primary-care consultations, a perceived reduction in symptoms, and significant health-service savings [286]. Increased physical activity has been reported to enhance intestinal gas clearance and reduce symptoms in patients with IBS complaining of bloating [287]. Whenever possible, the physician should resist the temptation to rely on drugs which might provide only limited efficacy and which could provoke unacceptable side effects. Nonetheless, medications are prescribed at 75% of outpatient visits for IBS [17]. High placebo response rates ranging from 30% to 70% have diminished the ability of controlled studies to detect therapeutic benefits of drug therapies of IBS [288]. Reviews have judged that few studies offer convincing evidence of drug efficacy, although some benefit for antispasmodics in reducing pain and for loperamide in controlling diarrhea can be concluded [289,290]. Critiques of published IBS drug trials raised methodological concerns about the peer-reviewed literature including studies which were too short in duration to detect efficacy, poorly designed cross-over protocols in which washout periods between active drug and placebo were inadequate, inappropriate statistical methods, and large placebo effects which would mandate the enrollment of hundreds of patients to detect a statistically significant drug effect [288]. In the design of new studies, they recommended careful description of the randomization method, use of international diagnostic criteria, use of placebo control and double-blinding, and definition of clear outcome measures.

Dietary measures and fiber supplements in irritable bowel syndrome

Dietary modifications are commonly recommended in IBS, although little controlled investigation has been performed. It is reasonable to limit fat intake as lipids most potently activate exaggerated motor reflexes such as the gastrocolonic response. Patients with bloating and diarrhea should restrict their intake of poorly digestible sugars such as fructose and sorbitol. A subset of patients with excess gas may derive benefit from additional dietary modification. Certain foods promote intestinal gas production. Pork and bean meals increase colonic gas passage from 15 to 176 mL/h as a consequence of maldigestion of oligosaccharides such as stachyose and raffinose [291]. Fiber content in the diet also can contribute to gas generation. A high-fiber diet with beans produces 49.4 mL gas per hour vs 10.9 mL/h on a liquid low-fiber diet [292]. However, most IBS patients who complain of excess flatus in fact produce normal amounts of gas. Exclusion of foods associated with increased flatulence including beans, onions, celery, carrots, raisins, bananas, apricots, prunes,

Table 60.3 Foods and flatus production

Normoflatulogenic foods
Meat, fowl, and fish
Vegetables (e.g., lettuce, cucumber, broccoli, pepper, avocado, cauliflower, tomato, asparagus, zucchini, okra, olives)
Fruits (e.g., cantaloupe, grapes, berries)
Carbohydrates (e.g., rice, corn chips, potato chips, popcorn, graham crackers)
Nuts
Miscellaneous (e.g., eggs, non-milk chocolate, flavored gelatin, fruit ice)
Moderately flatulogenic foods
Pastries
Potatoes
Eggplant
Citrus fruit
Apple bread
Extremely flatulogenic foods
Milk and milk products
Vegetables (e.g., onions, beans, celery, carrots, brussel sprouts)
Fruit (e.g., raisins, bananas, apricots, prune juice)
Miscellaneous (e.g., pretzels, bagels, wheat germ)

Adapted from Van Ness & Cattau [293].

brussel sprouts, wheat germ, pretzels, and bagels has been reported to reduce flatus expulsions in uncontrolled reports of patients with excess gas (Table 60.3) [293].

Fiber supplements are widely recommended for treating IBS and exhibit several properties which theoretically should be beneficial in IBS, including enhanced water retention and bulking of the stool, formation of gels to provide stool lubrication, and binding bile acids which could cause symptoms in some cases [294]. Notably, patients with IBS do not consume less dietary fiber than healthy individuals [295]. Studies in animal models have observed induction of propagative colonic motor activity with augmentation of dietary fiber content [296]. In a review of human investigations, bran increased fecal weight in 18 of the 20 studies and accelerated fecal transit in 16 [297]. Bran accelerated colonic transit in healthy volunteers with an initial colonic transit time of at least 3 days, whereas it retarded propulsion in those with a transit time of 1 day, suggesting that dietary fiber promotes a more regular bowel pattern in normal individuals [298]. Psyllium reduces perception of rectal distention, indicating that fiber may have positive effects on visceral afferent function as well [299].

Fiber supplements that have been studied in IBS in a placebo-controlled fashion include bran, psyllium, processed flea seed husk (ispaghula), and calcium polycarbophil. Because of high placebo response rates and the enrollment of small numbers of patients, studies have failed to document a therapeutic benefit of fiber supplementation in the IBS population as a whole [288]. Most investigations report increases in stool weight, decreases in colonic transit times, and improvement in constipation [300–303]. Others have noted benefits in patients with alternating diarrhea and constipation, pain, and bloating; however, most studies observe no responses in patients with diarrhea-predominant or pain-predominant IBS [304]. It is possible that different fiber preparations may have dissimilar effects on selected symptoms in IBS. One study observed symptom exacerbation in 55% of patients with IBS with bran but only 10% experienced symptom improvement [305]. A cross-over comparison of different fiber preparations found that psyllium produced greater improvements in stool pattern and abdominal pain than bran [306]. Furthermore, bran exacerbated complaints of abdominal distention but psyllium supplements reduced such complaints. A third study reported increases in flatulence with bran therapy [307]. Patients with IBS were noted to benefit from being placed on a fiber-restricted diet but with the use of commercial bulking agents as needed, suggesting that low-fiber diets may be advisable in some patients [308].

Medication treatments in irritable bowel syndrome

Osmotic laxatives

For patients with constipation-predominant IBS who do not respond to fiber, osmotic laxatives are often recommended to effect defecation. Available agents include hypertonic salt solutions such as milk of magnesia, poorly absorbable sugars such as lactulose and sorbitol, and isotonic electrolyte solutions containing polyethylene glycol. There is little controlled literature to support the use of osmotic laxatives specifically in IBS, although several studies do report benefits for polyethylene glycol which is a large polymer that is poorly absorbed and metabolically inert, in accelerating colonic transit and increasing stool frequency in patients with idiopathic slow transit constipation [309]. There are multiple placebo-controlled clinical trials of polyethylene glycol compounds showing this compound to be superior to placebo in increasing stool frequency and stool consistency in patients with chronic constipation [310,311]. The use of polyethylene glycol solution to relieve functional chronic constipation is generally safe and no blood electrolyte changes have been reported. Some patients may experience bloating or nausea.

Chloride channel activators

Lubiprostone, a member of a new class of compounds of bicyclic fatty acids called prostones, selectively activates type 2 chloride channels in the enterocytes without affecting the cystic fibrosis transmembrane conductance regulator [312]. As the Cl^- leaves the cell to enter the lumen, Na^+ and H_2O are also secreted into the lumen paracellularly to maintain the electrical gradient within the cell (Fig. 60.7). In this manner lubiprostone increases intestinal fluid secretion and facilitates intestinal transit, thereby increasing the passage of stool and alleviating symptoms associated with chronic constipation [313]. Clinical studies support the safety and efficacy of

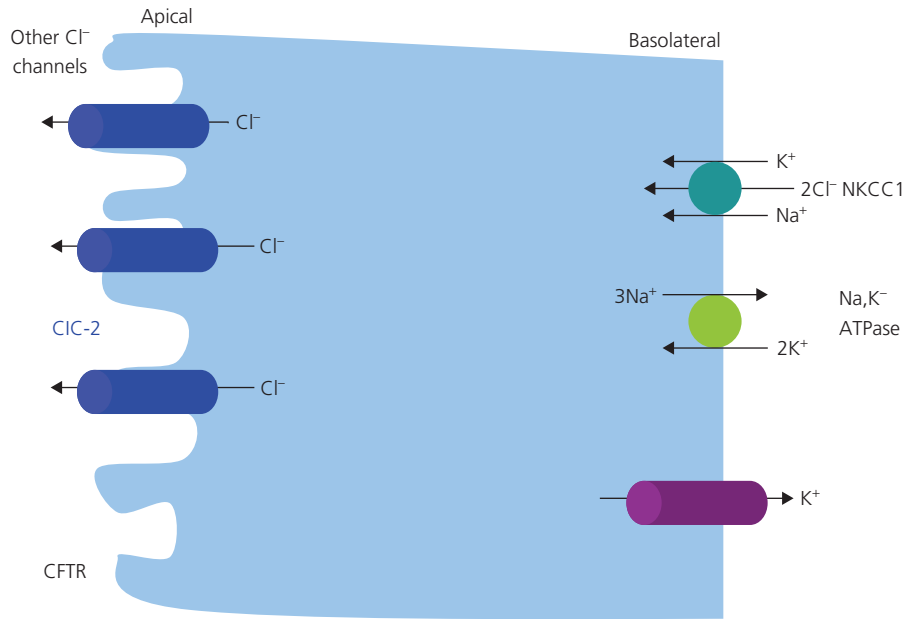

Figure 60.7 Chloride channels are located in the apical and serosal membranes of the enterocyte and facilitate Cl^- transport. Lubiprostone selectively activates type 2 Cl^- into the lumen. To maintain the electrical gradient Na^+ and H_2O are also simultaneously secreted into the lumen paracellularly.

lubiprostone for treatment of functional constipation. In a randomized, double-blind, placebo-controlled trial involving a total of 129 patients, it was demonstrated that lubiprostone 24 μg given twice daily for 21 days was more effective than placebo in inducing spontaneous bowel movement, decreasing straining and abdominal discomfort, and improving stool consistency [314]. Long-term studies indicate that efficacy was maintained for up to 48 weeks of treatment. The most commont side effects were nausea, diarrhea and headache.

Antidiarrheal agents

Peripherally acting opiate-based agents are the initial therapy of choice for diarrhea-predominant IBS. Physiological studies demonstrate increases in segmenting colonic contractions, delays in fecal transit, increases in anal pressures, and reductions in rectal perception with these drugs. Placebo-controlled investigations of loperamide report decreases in stool frequency and urgency, improved consistency, reduced borborygmi, and benefits for well-being in patients with diarrhea or alternating diarrhea and constipation [315]. Other agents have been proposed for use in IBS patients with diarrhea. An uncontrolled study of diarrhea-predominant IBS patients noted a 70% response to bile-acid-sequestering drugs [272]. Acid-suppressing drugs in the H_2-receptor antagonist and proton pump inhibitor classes have been reported in an uncontrolled trial to reduce diarrhea in IBS [316].

Antispasmodic agents

Antispasmodic agents are the most commonly prescribed agents for IBS and are the initial recommended therapy for pain-predominant IBS [282]. Included in this category are agents that block cholinergic nerve function, drugs that prevent calcium flux, direct gut smooth muscle relaxants, and agents that act by way of unknown pathways. From a physiological standpoint, anticholinergic drugs and calcium channel antagonists are potent inhibitors of the gastrocolonic response [317,318]. A metaanalysis of 26 double-blind clinical trials of antispasmodic agents in IBS reported better global improvement (62%) and abdominal pain reductions (64%) compared to placebo (35% and 45%, respectively), although none of the medications analyzed (cimetropium, pinaverium, trimebutine, octylonium, and mebeverine) are approved for use in the United States [319]. A second metaanalysis of controlled trials of cimetropium, hyoscine, mebeverine, otylonium, pinaverium, and trimebutine quantified improvements in global well-being in 56% vs 38% on placebo and reductions in pain in 53% compared to 41% on placebo [320].

Anticholinergic agents are the major class of antispasmodics prescribed in the United States. In small trials, dicyclomine, prifinium, and cimetropium have been reported to reduce symptoms including fecal urgency and pain in IBS compared to placebo [321,322]. However, issues of blinding, study duration, and statistical analysis raise questions as to the validity of these conclusions [288,321]. The gut-selective anticholinergic M_3 muscarinic receptor antagonist zamifenacin was demonstrated to blunt the colonic motor response to meal ingestion and shows promise as therapy for pain-predominant illness [322]. In animal models, M_3 receptor antagonists inhibit diarrheal responses to stress, serotonin, prostaglandins, and castor oil [323].

Calcium channel blockers have been proposed for use in IBS because of their smooth muscle relaxant properties and their inhibitory effects on the gastrocolonic response. A

double-blind trial of diltiazem did not show global improvement, but did record trends to reduced diarrhea and abdominal pain [324]. In a randomized, placebo-controlled trial, pinaverium reduced the duration of abdominal pain in IBS [325]. Octylonium produced significant improvements in the number of pain episodes, the severity of distention, and global assessments in a placebo-controlled trial in 325 patients [326]. Peppermint oil relaxes gastrointestinal smooth muscle through reduction of calcium influx [327]. In a recent large trial, 79% experienced pain reduction, 83% reported less abdominal distention, 83% had reduced stool frequency, and 79% passed less flatus, values which were all superior to placebo [328]. A metaanalysis of eight randomized, controlled trials reported a trend toward therapeutic benefit of peppermint oil in IBS, however this could not be definitively concluded because of methodological concerns [329]. Peppermint oil may also be of benefit in children with IBS, as the agent has been shown to reduce abdominal pain severity in 75% of cases [330].

Other antispasmodics unavailable in the United States that do not act by inhibition of cholinergic activity or calcium flux have been used for IBS. Mebeverine is a smooth muscle relaxant similar to papaverine that inhibits ileal and colonic motility in patients with IBS [331]. Two small studies have reported benefits for mebeverine over placebo whereas a third investigation observed no improvement [331,332]. Both the short- and long-acting forms of mebeverine were reported to be "effective" or "very effective" by more than 80% of patients with IBS in a non-placebo-controlled trial [333]. Trimebutine is an antispasmodic which stimulates small intestinal motility by acting on peripheral opiate receptors but inhibits colonic motility by way of a naloxone-insensitive pathway [334]. In the largest placebo-controlled trial involving 60 patients with IBS, there were no differences in pain relief with trimebutine vs placebo [335].

Antidepressant agents

Antidepressant agents in the tricyclic class have demonstrated clear efficacy in selected IBS subsets (Fig. 60.8), but the mechanisms of their beneficial effects are uncertain. In diarrhea-predominant IBS patients, imipramine slows propagation of jejunal pressure waves and delays orocecal and whole gut transit indicative of a motor inhibitory effect [336,337]. Some investigations have reported reduced perception of lumenal distention suggestive of inhibition of visceral afferent transmission, although other studies have shown no effects on visceral perception [338,339]. The effects of tricyclic antidepressants on central neural processing of painful viscera were studied. In a fMRI sudy of 19 females with painful IBS randomized to amitriptyline 50 mg or placebo for 1 month, rectal pain induced significant activation of the perigenual ACC, right insula, and right prefrontal cortex, and treatment led to reduced pain activation of the perigenual ACC and left posterior parietal cortex

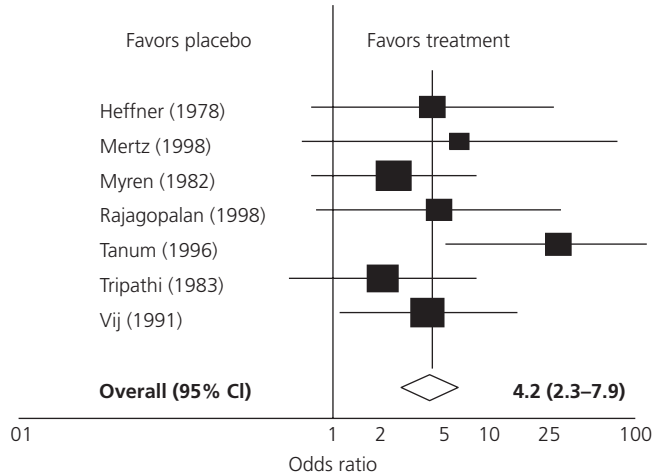

Figure 60.8 The results of metaanalysis of antidepressant medications on the overall improvement in gastrointestinal symptoms are shown. The boxes represent the odds ratios favoring active drug or placebo and the horizontal lines show the 95% confidence intervals. The box sizes are proportional to each study's weight in the analysis. When the data are pooled, the odds ratio for a benefit of antidepressant treatment is 4.2 with a 95% confidence interval ranging from 2.3 to 7.9. From Clouse et al. [357], with permission from Elsevier.

only during stress [340]. Since the perigenual ACC is part of the corticolimbic network that modulates the affective and cognitive components of pain perception during stress, amitriptyline appears to exact its beneficial effects on IBS by uncoupling the negative effects of stress on pain by way of the ACC. A controlled trial of amitriptyline reported benefits in global well-being, abdominal pain, and bowel pattern and identified young age and increased extroversion as predictors of drug response [341]. Studies of trimipramine have reported improvements in vomiting, depression, sleeplessness, and fecal mucus with variable reductions in pain compared to placebo [342]. Placebo-controlled trials of desipramine recorded decreases in pain, stool frequency, and depression which were confined to diarrhea-predominant patients [343]. Nortriptyline given in combination with fluphenazine was reported to reduce pain and diarrhea compared to placebo [344]. A large placebo-controlled, randomized study on desipramine (a tricyclic) showed that the medication (50–150 mg) was effective over placebo in treating women with moderate to severe IBS [345,346]. A clinical response appeared to be dependent on the presence of detectable blood levels of the medication. The general consensus is that patients with predominant diarrhea or pain may experience benefit with the tricyclic antidepressants. Additionally it is likely that patients with IBS who have well-defined depression will experience clinical improvement on tricyclic therapy.

The efficacy of antidepressant agents in other classes for treating IBS is less clear [328–330]. In contrast to tricyclic agents, the selective serotonin reuptake inhibitor (SSRI)

paroxetine accelerates orocecal transit raising the possibility that this drug class may be useful in constipation-predominant patients [337]. There is a paucity of randomized placebo-controlled trials of SSRI in IBS [347]. In one trial of patients who had failed to respond to a high-fiber diet, Tabas and colleagues [348] found that a low dose of paroxetine was superior to placebo in terms of overall well-being, IBS-related anxiety, and less food avoidance. These effects were observed even among nondepressed patients. The study by Kuiken and colleagues [349] found that in 40 nondepressed patients with IBS, fluoxetine did not significantly alter rectal sensitivity and symptoms in the patients in a double-blind, randomized placebo-controlled study. On the other hand, the trial by Tack and colleagues [350] showed that citalopram, an SSRI, was significantly superior to placebo in reducing the number of days with abdominal pain and the number of days in which IBS impacted on daily life. Again the improvement in IBS symptoms was not associated with improved mood. Based on the available studies reported so far, it appears that SSRI antidepressants do promote general well-being in some patients with IBS and possibly improvements in abdominal pain and bowel symptoms, and this effect is independent of improved depression. There are a number of possible mechanisms that might explain the beneficial effect of SSRI on IBS. In contrast to the tricyclic agents, paroxetine accelerates orocecal transit in both healthy subjects and patients with IBS, raising the possibility that this antidepressant class may have fewer deleterious effects in patients with IBS-C [318]. However, this mechanism is unlikely to be the principle therapeutic action of SSRI. The SSRI such as citalopram decrease the sensitivity of the colon to distention in healthy subjects [351] but in clinical trials, the result of intravenous citalopram did not predict outcome [350]. There is some evidence that SSRIs have an analgesic effect. This is not as strong as that of tricyclic antidepressants when used in IBS [337], or on neuropathic pain and back pain [352] but SSRI appear to be effective in patients with somatoform disorder [353]. Perhaps this action may be more important than any of the possible effects on the gut as citalopram may reduce the reporting of multiple bodily symptoms or "somatization" [354].

An investigation of mianserin, with serotonin 5-HT_2 and 5-HT_3 receptor antagonist and α_2-adrenergic receptor antagonist effects, reported reductions in pain, distress, and functional disability compared to placebo [355]. A metaanalysis of tricyclic and nontricyclic antidepressants reported an odds ratio for clinical improvement of 4.2 (confidence interval 2.3–7.9) (Fig. 60.8) [356]. On average, 3.2 patients needed to be treated to produce symptom improvement in one patient. A second metaanalysis of all antidepressant trials in IBS reported an odds ratio for improvements in pain of 8.0 and for global improvement of 4.4 [367].

Serotonin receptor agonists and antagonists

Serotonin exists in abundance in the enterochromaffin cells of the gastrointestinal mucosa. It is a paracrine messenger which functions as sensory transducer [358]. Because 5-HT activates intrinsic and extrinsic primary afferent neurons to initate peristaltic and secondary reflexes, and to transmit sensory information to the central nervous system (Fig. 60.9), serotonin receptor agonists and antagonists have been developed to treat pain and motility abnormalities in IBS.

The 5-HT acting on 5-HT_3 receptors enhances the sensitivity of afferent neurons projecting from the gut to the central nervous system (Fig. 60.9) [359]. In humans, 5-HT_3 receptor antagonists such as alosetron reduced the perception of

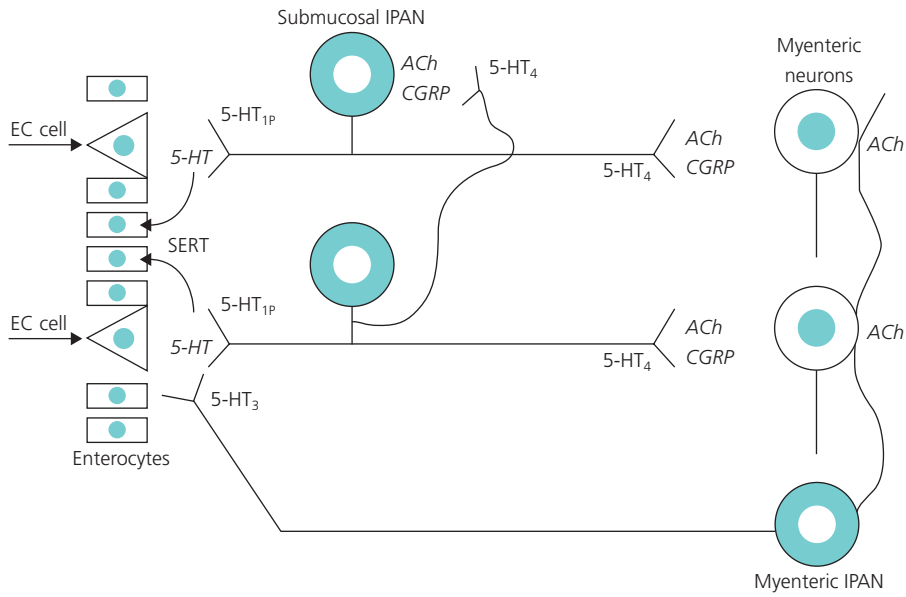

Figure 60.9 Major serotonin (5-HT) receptor subtypes in the enteric neural circuits. The 5-HT secreted from epithelial 5-HT containing enterochromaffin (EC) cells can stimulate extrinsic (not shown) or intrinsic primary afferent neurons (IPAN), which are found in the submucous and myenteric plexus. Submucosal IPANs are activated by 5-HT_{1P} receptors, whereas myenteric IPANs are activated by 5-HT_3 receptors. Release of acetylcholinesterase and calcitonin gene-related peptide from IPANs is amplified by 5-HT_4 receptors, which are presynaptic. Myenteric IPANs have multiple projections that terminate on numerous other cells. They are activated by 5-HT_3 receptors. Submucosal IPANs mediate peristaltic and secretory reflexes. Myenteric IPANs are associated with giant migrating contractions. Adapted from Gershon & Tack [358], with permission from Elsevier.

painful visceral stimulation in IBS [360–362]. It also induced rectum relaxation, increased rectal compliance and delayed colonic transit [363,364]. A number of placebo-controlled trials of alosetron reported reductions in discomfort and improvements in stool frequency, consistency, and urgency in nonconstipated patients with IBS [365–368]. A follow-up study of 48 weeks duration confirmed the long-term efficacy of alosetron. For unclear reasons, women with IBS derived greater benefit than men. However, in postrelease surveillance, 84 cases of ischemic colitis were observed including 44 cases that required surgery and four deaths. As a consequence, the medication was voluntarily withdrawn by the manufacturer in 2000 [369]. Alosetron was reintroduced under a new risk management program where patients have to sign a patient–physician agreement. This has significantly limited its usage.

The 5-HT_4 receptor agonists stimulate motility and secretion through enhanced release of acetylcholine from excitatory motor neurons and interneurons (Fig. 60.9) [370]. In this manner they strengthen cholinergic neurotransmission in enteric neural circuits in the myenteric plexus and so are prokinetic. In patients with IBS who have constipation, tegaserod (a 5-HT_4 agonist) accelerated intestinal and ascending colon transit. Clinical trials involving more than 1200 patients with constipation-predominant IBS have reported that tegaserod given at 2 mg and 6 mg twice daily produced a dose-dependent improvement in constipation and bloating in 40% of patients compared to 27% on placebo [371,372]. Symptom improvements were maintained in an open-label 13-month extension study [373]. Diarrhea and headache were the only significant side effects observed in these studies; however, there were a few cases of ischemic colitis reported in the postmarketing surveillance [374]. The drug was withdrawn by the manufacturer because of concerns with coronary and cerebrovascular events.

Serotonin plays an important role in modulating gut motility, sensation, and secretion so the 5-HT receptor agonists and antagonists are attractive candidates for the treatment of functional bowel diseases such as IBS. However, the reported vascular complications associated with the use of 5-HT_3 antagonists and 5-HT_4 agonists raise some safety issues. More selective 5-HT receptor agonists and antagonists are being studied for the treatment of functional gastrointestinal disorders.

Modulation of gut flora

Probiotics, which are defined as live or attenuated bacteria or bacterial products that confer a significant health benefit to the host, have been used to treat patients with IBS. There are a number of theoretical therapeutic benefits in IBS.

- Many probiotics exert antibacterial and antiviral effects and could prevent or modify the course of postinfectious IBS [375,376].
- Probiotics may have antiinflammatory effects on the mucosal surface [377,378] and so reduce immune-mediated activation of enteric motor and sensory neurons and modify neural traffic between the gut and the central nervous system.
- Probiotics could alter volume or composition of stool and gas [379] and increase intestinal mucus secretion [380]. This may help to modulate symptoms such as constipation and diarrhea.

Clinical evidence of benefit of probiotics in IBS, however, has been less than compelling. Until recently, the best documented double-blind, randomized, placebo-controlled study in 60 patients with IBS reported that flatulence was the only symptom improved with probiotics [381]. A follow-up study using the same *Lactobacillus plantarum* preparation failed to show any change in colonic fermentation, nor did it confirm any clinical benefit [382]. *Lactobacillus plantarum* was also used in another study, which showed a 100% response rate vs just 16% in the control [383]. This remarkable response rate is an outlier among all IBS studies and needs confirmation. A more recent study using VSL #3, a probiotic mixture including lactobacilli and bifidobacteria, in 48 patients with IBS showed that VSL #3 reduced flatulence and retarded colonic transit without altering other gastrointestinal symptoms such as abdominal pain, bowel movements, and bloating scores [384]. Perhaps the most encouraging study to date is that by O'Mahony and colleagues [377], who compared the effect of two probiotics, *Lactobacillus salivarius* against *Bifidobacterium infantis*, in 77 patients with IBS in a double-blind, randomized, placebo-controlled trial. The treatment phase was 2 months, preceded by a 4-week run-in period and followed by a 4-week washout period. Patients taking *B. infantis* experienced a greater reduction in symptom scores for abdominal pain, bloating/distention, and bowel movement difficulty for every week during treatment and during the 4-week washout period, whereas the *L. salivarius* group appeared no different from placebo. This beneficial effect appeared within the first week of treatment and reached its maximum after 2 weeks. In addition, for the first time, a marked immunological difference between IBS and controls was reported. Patients with IBS demonstrated an abnormal IL-10 : IL-12 ratio in the blood, indicative of a proinflammatory T helper type 1 state. This ratio was normalized by *B. infantis* feeding alone, suggesting an immune-modulating role for the organism. This exciting finding requires confirmation with a larger study involving patients with IBS stratified on the basis of inflammatory and immune markers before and after treatment.

Other medication treatments of irritable bowel syndrome

Because IBS symptoms are often associated with menstrual cycling, investigators have searched for hormonal treatments for IBS. Continuous gonadotropin-releasing hormone administration reduces synthesis of the gonadotropins, follicle-stimulating hormone, and luteinizing hormone, with inhibition of cyclic gonadal hormone variations. Small trials

of the gonadotropin-releasing hormone analogue leuprolide in patients with functional gastrointestinal symptoms showed improvements in nausea, abdominal pain, early satiety, bloating, and altered bowel habits for up to 1 year [360,361]. A large multicenter trial of leuprolide reported improvements in abdominal pain, nausea, altered bowel habits, and quality of life in patients with functional bowel disease [362]. The mechanisms of action of leuprolide are uncertain. In an immunosuppressed patient with intestinal pseudoobstruction, leuprolide evoked intense, propagative upper gut motor activity [363]. It is unlikely that this action is responsible for the clinical benefits of the drug in IBS because most patients with IBS do not exhibit pronounced dysmotility. As it induces amenorrhea and osteoporosis, leuprolide is unlikely to achieve widespread long-term use in IBS.

Several agents have been promoted to reduce gas and bloating. Anticholinergics blunt the gastrocolonic response to a meal and reduce the increase in flatus caused by ingestion of beans [293]. Uncontrolled studies using silicone agents such as simethicone show reduction in excess bloating and flatus [364]. Activated charcoal has a large surface area to mass ratio (450–1800 m^2/g) which allows it to be an excellent adsorbent of gas [385]. Small doses of activated charcoal decrease the number of flatus passages after ingestion of beans in healthy volunteers. The microbial α-galactosidase agent Beano reduces hydrogen production after black bean ingestion by healthy volunteers. In a controlled trial in healthy volunteers, pancreatic enzymes reduced bloating, gas, and fullness after eating high-fat, high-calorie meals compared to placebo [386]. No trials of Beano or pancreatic enzymes have been reported in IBS. In a recent study, the nonabsorbable antibiotic rifamaxin reduced hydrogen production, flatus emissions, and abdominal distention to greater degrees than activated charcoal in healthy volunteers and patients with functional bowel disease [387].

Mast cell degranulation inhibitors have been proposed as treatments for diarrhea-predominant patients by investigators who postulate a role for food allergy in IBS. One study evaluated 101 patients with diarrhea-predominant IBS with evidence of food hypersensitivity on the basis of exclusion diets [388]. Of those with positive skin prick tests for food allergy, 67% reported improved symptoms on sodium cromoglycate whereas only 41% with negative skin tests experienced relief. In a second uncontrolled report, sodium cromoglycate produced improvement in 67% of patients with diarrhea-predominant IBS when given for 1 month, especially in those with food allergy [389]. The response to sodium cromoglycate may be more impressive in pediatric populations with IBS symptoms where true food intolerance may be more prevalent. A multicenter trial reported that 97% of children (mean age 4 years) exhibited a clinical response to the drug over a 1-month period [390]. These results, however, require confirmation in placebo-controlled trials.

Tranquilizers have been used for decades to treat IBS. Older studies reported benefits for phenaglycodol, meprobamate, heteronium plus amobarbital, propantheline plus phenoarbital, chlordiazepoxide, diazepam, medazepam, and aprazolam; however, many of these studies were small or poorly designed [391–393]. Buspirone increases colonic compliance; however, its efficacy in reducing symptoms has not been convincingly demonstrated in IBS [394]. Coupled with their abuse potential and development of tolerance, the use of sedatives is not indicated in most patients with IBS.

Potential future therapies for irritable bowel syndrome

Recent investigation has focused on medications which blunt visceral hyperalgesia in IBS. Such "antiafferent" agents might act by way of one or more mechanisms including:

- modification of release of pain-inducing mediators in the gut wall
- blockade or activation of peripheral afferent nerve receptors
- inhibition of afferent nerve transmission
- modification of afferent activity in the central nervous system [114].

Some available drugs, including calcium channel antagonists and opiate agents, reduce visceral perception in association with reducing gut motor function or altering central nervous system processing of pain [395].

κ-Opioid compounds inhibit somatic pain through their action on peripheral sensory nerve endings [396]. In patients with IBS, the κ-opioid analogue fedotozine increases the thresholds to colonic distention for first perception and pain without affecting compliance [397]. It also modifies neural reflexes in experimental gut inflammation, chemically induced peritonitis, and postoperative ileus [398]. In a double-blind, placebo-controlled, multi-center trial in 238 patients with IBS, fedotozine reduced pain and overall disease severity over a 6-week period [399].

α_2-Adrenergic receptor agonists also have been proposed to reduce perception of visceral pain. In healthy volunteers, the α_2-adrenergic receptor agonist clonidine increased colonic and rectal compliance and decreased tone, urgency, and pain during balloon distention [400]. This suggests possible utility for this class of drugs in pain-predominant IBS. Conversely, the α_2-adrenergic receptor antagonist yohimbine increased tone and perception of colorectal distention. Another α_2-adrenergic receptor agonist lidamidine reduced perception of rectal distention compared to placebo in 50 patients with IBS [401]. This drug has been reported to have benefit in treating patients with IBS [402].

Substance P has been postulated to participate in the mediation of visceral pain through activation of neurokinin receptors. In animal models, neurokinin NK_1 receptor antagonists decrease stress-induced defecation as well as reduce the colonic response to the central nervous system stress mediator CRH [403]. Preliminary studies of the NK_1 receptor

antagonist CJ-11,974 have reported benefits in reducing symptoms in patients with IBS with trends to reductions in visceral sensitivity [404].

Physiological studies suggest that other agents may have visceral analgesic effects. The somatostatin analogue octreotide reduces the perception of rectal distention through inhibition of visceral afferent pathways in healthy volunteers [405]. Patients with IBS who have fecal urgency were shown to exhibit a similar response to octreotide [406]. Additionally, octreotide reduced the increased pressures that resulted from rectal distention in these patients. In a second study, octreotide blunted perception of rectal distention without altering lumenal compliance in an IBS population with more constipation-predominant patients [407]. Subsequent work using cortical and spinal evoked potentials showed that octreotide specifically inhibits spinal afferent transmission from the rectum, documenting a peripheral site of action for the somatostatin analogue [408]. Finally, intravenous oxytocin increases the thresholds for perception of colonic distention by way of opiate-independent pathways without affecting lumenal compliance [409]. To date, no placebo-controlled trials of the clinical efficacy of these agents have been performed, so their utility in IBS is unproved.

Psychological therapy of irritable bowel syndrome

Psychological therapy has been most commonly employed for patients with IBS with psychosocial features who do not respond to standard therapies. A systematic review of controlled psychological treatments in the literature from 1966 to 1994 uncovered only 14 studies that exhibited appropriate study design [410]. Eight studies reported that psychological treatment was superior to control treatment whereas six observed no benefits. Because of methodological inadequacies, it was felt that the efficacy of psychological therapy of IBS was not established and that further trials were needed. With recent advances in psychological treatments, better results have been obtained [411–413]. Some studies report that improvements achieved with psychological treatments are similar or even greater than the improvement obtained with gut-directed pharmacological treatment (e.g., tegaserod and alosetron) [414,415]. A metaanalysis of cognitive behavior therapy for IBS reported efficacy data (> 50% reduction of gastrointestinal symptoms) from 17 studies yielded an odds ratio of 12 (5.6–26). The average number of patients needed to treat with cognitive behavior therapy or hypnotherapy for one patient to achieve improvement over the waiting list or other control groups was estimated to be 2 [416]. These outcomes compared favorably with those obtained using alosetron [415] and tegaserod [414]. As a result, many investigators have proposed a range of treatment for IBS including psychotherapy, cognitive therapy, biofeedback, and hypnosis.

Psychotherapy has shown promise in patients who do not respond to medications. In 101 patients with IBS, 3 months of dynamically oriented psychotherapy plus medications provided greater improvements in somatic symptoms than medical treatment alone [417]. A second psychotherapy study of medically refractory patients reported reductions in abdominal pain and diarrhea, but not constipation, as well as improvement in depression [418]. A long-term follow-up of patients undergoing psychotherapy showed maintenance of symptom control at 1 year, whereas individuals who declined psychotherapy had relapsed. Group psychotherapy, including techniques such as psychodrama in which the patient involves other group members in his or her bowel symptoms, does not reduce abdominal pain or improve bowel habits although anxiety levels may decrease [419].

Cognitive therapy produces improvements in bowel symptoms in some patients with IBS. When compared with daily symptom monitoring, cognitive therapy produced clinical improvement in 80% of patients vs 10% of the symptom-monitoring group [420]. Similarly, patients with IBS undergoing cognitive therapy experienced greater reductions in bowel symptoms than did patients assigned to a self-help support group or to a symptom-monitoring wait list [421]. The benefits of cognitive therapy have been reported to persist in long-term follow-up after completion of the treatment [422]. Although multiple clinical trials support the efficacy of psychological treatments for reducing IBS symptoms, the mechanisms responsible for symptomatic improvement remains unclear. To address this issue, Lackner and colleagues [423] applied a mediation analysis to a subsample of data from a randomized clinical trial of group-based cognitive behavior therapy for IBS [411]. These investigators reported that group-based cognitive behavior therapy in comparison to a psychoeducational group, as an attention-based placebo control condition, reduced gastrointesintal symptoms including abdominal pain, bowel dysfunction, nausea and belching independent of its effects on psychological distress and health-related quality of life. This provocative finding suggests that cognitive behavior therapy may have a direct effect on global IBS symptoms that is not related to its beneficial effect on psychological distress. In a brain imaging study using PET [424], the same group of investigators demonstrated that neural activity in the parahippocampal gyrus and inferior portion of the right cortex cingulate gyrus was reduced in the postcognitive therapy scan, compared to the pretreatment scan. The changes in limbic activity were accompanied by improvements in gastrointestinal symptoms, whereas the left pons showed decreased neural activity, which was correlated with the posttreatment anxiety score. This suggests that changes in neural activity of corticolimbic regions, which subserve hypervigilance and emotion regulation, may be responsible for the symptom improvement with cognitive therapy. It is conceivable that strengthening of corticolimbic–pontine inhibition circuits by this form of psychotherapy directly reduces central pain amplication mechanisms [425]. A recent trial compared therapeutic

responses on standard medical therapy to standard medical therapy plus a multicomponent program consisting of IBS education, muscle relaxation, cognitive coping strategies, and assertiveness training [426]. The combination therapy group reported superior reductions in symptoms and improved quality of life, although perception of rectal distention was unaffected by either therapy. Another study suggested that listening to a therapeutic audiotape on IBS provided results that were nearly as good as those achieved with hypnotherapy [427].

Biofeedback and stress reduction techniques have been employed by some clinicians. Muscle relaxation training and stress-reduction education reduced bowel symptoms in an uncontrolled study, especially in patients who exhibited improved depression and anxiety [428]. When followed up at 4 years, 50% reported sustained improvements in pain, diarrhea, nausea, and flatulence. Similarly, in another study, the frequency and severity of painful IBS attacks were decreased by relaxation treatment compared to antispasmodic drugs [429]. More recently, relaxation treatment was shown to reduce primary gastrointestinal symptoms to a greater degree than symptom monitoring [430]. However, other studies have shown no improvement in bowel symptoms. A recent 3-month relaxation response meditation program produced significant improvements in flatulence, belching, bloating, and diarrhea [431]. In a novel study, patients were trained to reduce symptoms by listening to their bowel sound pattern through a stethoscope and attempting to modify their borborygmus [432]. This bowel-sound biofeedback led to improved symptomatology in three of five patients enrolled, with long-term success in two of them. More recently, computerized biofeedback video games have been found in uncontrolled studies to reduce stress and improve relaxation in a significant fraction of patients with IBS [433].

Hypnosis has been proposed for refractory cases of IBS. In a study of 30 patients with IBS, hypnosis provided better improvements in abdominal pain, distention, and well-being but not bowel pattern after 3 months of treatment compared to psychotherapy [434]. When followed for 18 months after being instructed in autohypnosis, sustained remission was reported by most individuals although patients over 50 years old or with underlying psychopathology were less likely to respond. Subsequently the authors reported a success rate of 85% in more than 200 patients with IBS treated with hypnosis. Another controlled trial of hypnosis also reported improvements in abdominal pain, constipation, and flatulence [435]. No correlation was observed between initial susceptibility to hypnosis and treatment gain. In addition to improving symptoms of pain, bloating, bowel habit, nausea, and flatulence, one clinical trial of hypnosis reported beneficial effects on quality of life measures including physical and psychic well-being, mood, and work attitude [436]. Furthermore, patients treated with hypnosis missed less work and visited their physicians less frequently than control patients. An anorectal manometric study of 15 patients with IBS demonstrated reduced perception of rectal distention with hypnosis suggesting that hypnosis may inhibit afferent pathways mediating perception of visceral discomfort [186].

Alternative medicine in irritable bowel syndrome

Over the last 10 years, a wide variety of complementary and alternative medical practices and therapies including hypnotherapy, some forms of herbal therapy and specific diets have been used to treat IBS [437]. Among these, acupuncture is frequently used despite the fact that its efficacy has not been convincingly demonstrated. Human studies have shown that acupuncture modulates the endorphin system [438] by way of central processing pathways [439]. In a study by Chan and colleagues [440], immediate improvement of symptoms was observed in seven patients but this pilot study did not include a control group. A randomized controlled study in 25 patients did not find acupuncture to be effective but it employed atypical acupuncture treatment using a single acupuncture point [441]. In a double-blind, controlled study involving 43 patients with IBS, Schneider and colleagues [442] reported that both the acupuncture and sham acupuncture groups improved significantly in global quality of life (QOL) as assessed by the functional digestive diseases quality of life questionnaire (FDDQOL) at the end of treatment with no difference between the groups. It was concluded that acupuncture in IBS is primarily a placebo response. Further randomized control trials involving large number of patients stratified by sex and subgroup are needed to assess the therapeutic effects of acupuncture in IBS.

In Asian countries, traditional Chinese herbal medicine is used with increasing frequency, especially to treat IBS. In a large placebo-controlled, double-blind, multiarmed trial of a number of herbal remedies, measures of pain, stool function, or quality of life were not better with *Fumaria officinalis*, *Curcuma xanthorrhiza*, Ayurvedic, or spagyric remedies compared to placebo [443]. Similary, a randomized double-blind placebo-controlled trial involving 119 Chinese patients with IBS with predominantly diarrhea symptoms showed no significant difference in individual symptom score and the quality of life assessment between those receiving a standard preparation of traditional Chinese medicine extracts that contained 11 herbs and placebo [444]. Although complementary and alternative medical therapies are widely employed in the treatment of IBS, their efficacies remain to be proven.

Approach to different subsets of patients with irritable bowel syndrome

The management of the patient with IBS is dependent on the predominant symptom. In the technical review for practice

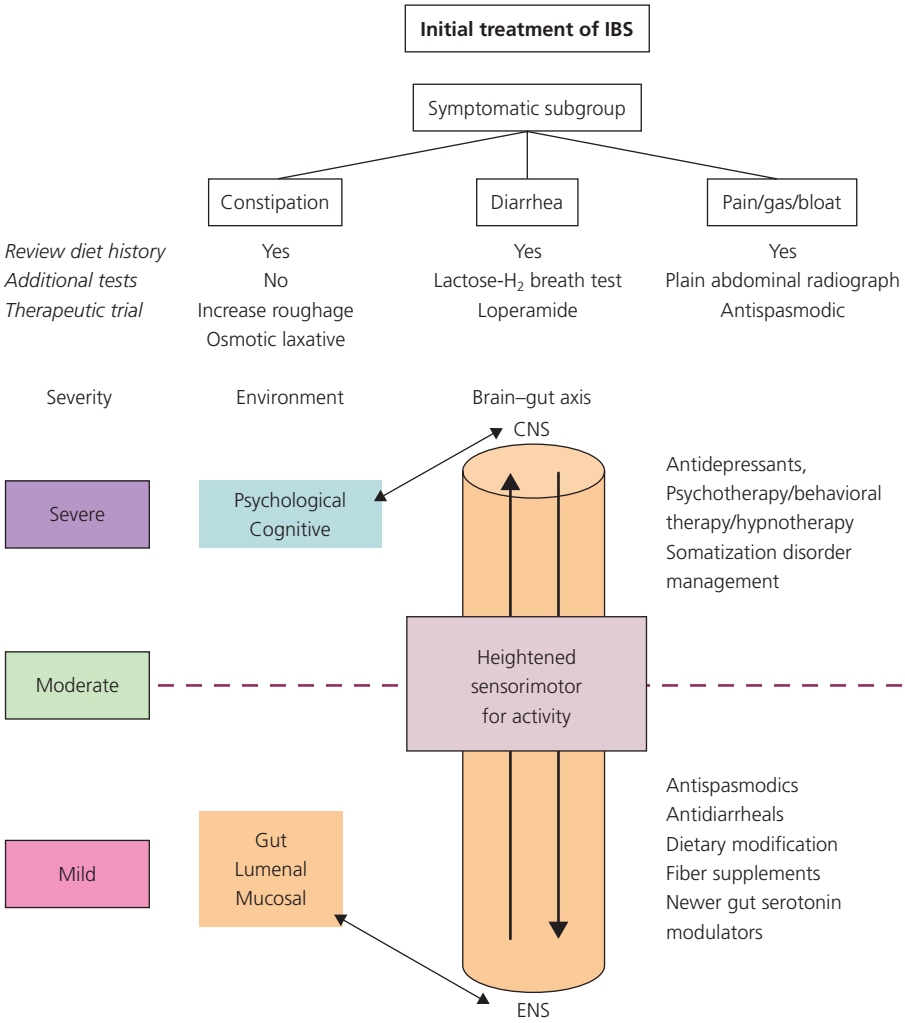

Figure 60.10 Recommendations of a technical review for practice guideline development for the initial management of irritable bowel syndrome (IBS) are shown based on the dominant symptom subtype. From Drossman et al. [282], with permission from Elsevier.

Figure 60.11 Therapeutic targets for irritable bowel syndrome. Patients with mild to moderate symptoms usually have intermittent symptoms that correlate with altered gut physiology. Treatments include gut-acting pharmacological agents such as antispasmodics, antidiarrheal, fiber supplements, and gut serotonin modulators. Patients who have severe symptoms usually have constant pain and psychosocial difficulties. This group of patients is best managed with antidepressants and other psychosocial treatments.

guideline development published by the American Gastroenterological Association, specific therapeutic trials of 3–6 weeks duration were proposed for each symptom subtype before embarking on a more extensive diagnostic evaluation (Fig. 60.10) [282]. Therapeutic targets for IBS are determined by severity of symptoms and their perceived pathomechanisms (Fig. 60.11). Patients with mild to moderate symptoms usually have intermittent symptoms that correlate with altered gut physiology. Treatments include gut-acting pharmacological agents such as antispasmodics, antidiarrheals, probiotics, fiber supplements, and osmotic laxatives. Patients with more severe IBS frequently have constant pain and psychological difficulties. They are best managed with tricyclic antidepressants and psychological therapy. An approach to different subsets of patients with IBS is detailed below.

The constipation-predominant patient

The management of the patient with constipation-predominant IBS involves measures to increase stool water and bulk and reduce the effort of defecation. The most widely used and efficacious compounds for this purpose are bulking agents in concert with a high-fiber diet. Patients should be cautioned that fiber supplements may take several weeks to produce satisfactory results and should be introduced gradually to prevent excess gas. Additionally, any medications that slow colonic transit should be discontinued. Patients with an inadequate response should be given an osmotic agent such as milk of magnesia or an isotonic solution containing polyethylene glycol in addition to the fiber program.

The chloride channel activator, lubiprostone, has been shown to be effective for functional constipation. This medication may be used in patients who fail to achieve satisfactory results. In patients with refractory constipation, further diagnostic testing may be needed to rule out other functional or structural diseases. Using radiopaque markers or colonic scintigraphy, generalized delays in colonic transit indicate the presence of slow-transit constipation (also known as colonic inertia) whereas localized delays suggest functional outlet obstruction in the distal colon. Defecography (cinefluoroscopy of the defecation process) can identify puborectalis muscle dysfunction, rectocele, or rectal prolapse as independent causes of constipation. In IBS, defecography

studies have shown an inability to widen the rectoanal angle as well as impaired perineal descent during simulated defecation indicative of diffuse alterations in pelvic floor mobility [445]. Anorectal manometry, in addition to demonstrating sensory abnormalities, can screen for Hirschsprung disease. These techniques are useful for detecting patients who might be better treated surgically or with a biofeedback program of bowel retraining. Laboratory studies can screen for porphyria or lead toxicity.

The diarrhea-predominant patient

Controlling diarrhea in IBS centers on reducing defecation frequency and urgency and improving stool consistency. Opiate agents such as loperamide are most effective as the initial therapy of diarrhea in IBS. Individuals with prominent meal-related symptoms may achieve benefit from antispasmodic agents in the anticholinergic and calcium channel antagonist classes. Tricyclic antidepressants and bile-acid-binding agents may also be useful in some diarrhea-prone patients. A careful dietary history should screen for foods containing lactose, sorbitol, or fructose. Other dietary manipulations are usually without benefit and are not encouraged in most patients. Use of sodium cromoglycate for food hypersensitivity is unsubstantiated in most diarrhea-prone patients.

Patients not responsive to these therapies may be considered for additional testing. Duodenal aspiration is rarely required to exclude giardiasis. Endomysial antibodies can screen for celiac sprue. Small intestinal biopsy and barium radiography may be performed to rule out Crohn's disease or celiac sprue. Stool volume and fat quantification can assist in the diagnosis of secretory processes or malabsorption. Laxative screens are indicated for the evaluation of refractory or atypical symptoms.

In patients who are resistant to antidiarrheal therapy, a colonic biopsy should be performed to rule out microscopic colitis because the clinical-symptom-based criteria for IBS are not specific enough to exclude the diagnosis of microscopic colitis [446].

The patient with painful irritable bowel syndrome

Controlling abdominal pain in IBS can be challenging. Narcotics should be avoided because of the risks of tolerance and dependence. Antispasmodic drugs are the preferred initial agents for pain-predominant IBS. In tertiary referral centers, antidepressants such as tricyclics have shown good results in those patients who have painful IBS and they may be the drug of choice for a subset of patients who have severe pain and diarrhea. The gonadotropin-releasing hormone analogue leuprolide can be considered for rare patients with refractory symptoms, especially those whose symptoms are prominently associated with menstrual cycling.

Further evaluation to investigate the cause of pain in medication-refractory cases should be directed at objective historical and examination findings. Upper endoscopy may detect acid peptic injury in cases of severe dyspepsia or heartburn. Liver and pancreatic chemistries and imaging tests such as abdominal ultrasonography or computed tomography are obtained if hepatobiliary or pancreatic disease is suspected. Computed tomography enterography or capsule endoscopy can detect atypical presentations of Crohn's disease, whereas gastric scintigraphy or gastrointestinal manometry may be obtained in the patient with associated nausea and vomiting. Exclusion of intestinal bacterial overgrowth may be obtained with hydrogen breath testing. Rarely, patients will need laboratory testing to exclude lead toxicity or porphyria.

Patient outcome in irritable bowel syndrome

Most long-term studies of IBS report that symptoms persist for more than 5 years in more than 75% of patients despite appropriate therapy. Only 34 of 103 patients were symptom-free on long-term follow-up in one study [447]. A second investigation followed 50 patients with IBS at 2-month intervals for 12–31 months [448]. In 44 patients, the qualitative nature of the symptoms did not change with long-term follow-up although symptom severity was variable. More recent studies indicate that not infrequently patients with IBS may change their bowel habits from diarrhea to constipation or vice versa. A follow-up of 4581 individuals with IBS reported that only 5% were symptom-free after 5 years [449]. This lack of significant improvement in patients with IBS may not hold true for all populations with IBS symptoms. In a study of elderly Danes, 50%–79% of subjects suffering from IBS on initial inquiry no longer experienced symptoms at the 5-year follow-up [450].

Even though symptoms persist in many patients with IBS, their quality of life can be enhanced by appropriate physician intervention. In one study, 18 of 44 patients noted reduced symptom intensity after 12–31 months of continued medical follow-up [448]. Of 34 fully employed patients, 20 lost no work in the first year after diagnosis. Only seven patients lost more than 2 weeks because of their symptoms, as a consequence of improved coping skills. A second investigation of 43 patients with IBS reported that abdominal pain and the overall sense of well-being were reduced after 5 years of follow-up but other symptoms were unchanged [451]. Those who had improved exhibited reduced anxiety compared to those who had not. Symptom resolution was observed in 20% of 97 patients with IBS who were studied for 5–7 years on a treatment program of antispasmodic drugs, bulking agents, and high-fiber diets and significant symptom reduction was reported in an additional 42% of individuals [447]. Patients who were male, had a short history of symptoms, had a history of recent acute onset of symptoms, exhibited predominant constipation, and noted a good initial response to treatment were most likely to achieve good long-term

improvement. Other studies have found that reductions in anxiety and fear of cancer correlate with improvement over a 6-month period [452]. On the other hand, a recent retrospective study found no independent association between a negative colonoscopy and reassurance or improved health-related quality of life in patients with IBS younger than 50 years [453]. In the longest follow-up reported to date (median 29 years), fewer return visits to physicians were reported for patients who had undergone inquiry about psychosocial issues and precipitating factors and who had been given detailed discussions about their diagnosis and treatment [284]. These studies suggest that counseling, reassurance, and education provided by the physicians, judicious use of medications, and continued interest in the patients' well-being may promote successful outcomes in many patients with IBS.

Epidemiology, 1574
Etiopathogenesis, 1574
Pathophysiology, 1575
Natural history, 1577
Diverticular diseases, 1579

A diverticulum (plural: diverticula) is a sac-like protrusion of the colonic wall. The spectrum of diverticular disease encompasses diverticulosis, diverticulitis, and diverticular bleeding. *Diverticulosis* describes the presence of diverticula. *Diverticulitis* refers to symptomatic inflammation of a diverticulum. "Complicated" diverticulitis refers to a diverticular abscess, fistula, small bowel or colonic obstruction, or free intraperitoneal perforation; "simple" diverticulitis is inflammation in the absence of these complications.

This chapter initially discusses the epidemiology, etiopathogenesis, pathophysiology, and natural history of diverticular diseases of the colon. A detailed discussion of the clinical presentation, diagnosis, and treatment follows, concentrating on the specific diverticular entities and addressing special situations dictating a more individualized approach. Attempts have been made to identify and discuss controversies.

Epidemiology

The epidemiology of diverticular disease of the colon has changed markedly since its initial recognition as a disease entity at the beginning of the 20th century. Indeed, the first reported surgical resection for complicated diverticulitis was performed by W. J. Mayo and colleagues in 1907 [1]. The apparent prevalence of diverticulosis increased from 5%–10% in 1918 [2] to 35%–50% in an autopsy series from 1969 [3]; there are no good recent, population-based studies. The prevalence of colonic diverticula increases with age from about 5% at 40 years of age, to 30% at age 60, and 65% by age 85 [4,5].

The predominance of males reported in early series has changed to either equal distribution or to a slight female preponderance in more contemporary studies [4]. In a study of 934 patients admitted to a single major medical center between 1988 and 1999, 63% were female [6]. The sex distribution appears also to vary with age. In one series, 60% of symptomatic patients were women [7] but, in patients under 50 years, men predominated with a male to female ratio of 2.2 : 1. In several other reports, male preponderance has also been noted in patients less than 40 years of age [8,9].

Geographic variations also exist both in the prevalence and anatomic pattern of diverticulosis. Westernized countries have prevalence rates of 5%–45%, depending on the method of diagnosis and age of the population [3,10]. Diverticular disease in these countries is predominantly left-sided, with right-sided diverticulitis present in only about 2% of symptomatic patients [11]. This distribution differs markedly in Africa and Asia [2,12], where the prevalence of diverticulosis is less than 0.2%, and diverticulitis is usually right-sided. With Japan and Singapore adopting a Western lifestyle, these cultures have experienced an increase in the prevalence of diverticulosis [13,14]. A review of 13 947 barium enema examinations performed over a 15-year period in Tokyo, Japan, revealed a steady increase in the incidence of diverticulosis of the right colon [15]. Somewhat surprisingly it remains right-sided [3]; moreover, 70% of symptomatic patients are less than 40 years old [14]. In Hong Kong, diverticulosis involves the right colon in 76% of patients [16], and right-sided diverticulitis accounts for 17% of patients with acute diverticulitis [17], a much greater percentage than in Western cultures.

Etiopathogenesis

Painter and Burkitt first speculated that low dietary fiber is a major factor predisposing to development of diverticulosis [5,18]. They recognized that where African natives had a diet high in dietary fiber and produced a large volume of daily stool output, diverticulitis was distinctly unusual. This concept, however, remains controversial [12,19,20]. One study of a cohort of 47 000 men provided strong evidence for a

Textbook of Gastroenterology, Fifth Edition Edited by Tadataka Yamada
© 2009 Blackwell Publishing. ISBN: 978-1-405-16911-0

primary role of lack of fiber in the etiopathogenesis of left-sided diverticulosis [21]; a diet low in fiber content increased the risk of symptomatic diverticular disease. Diverticular disease is also less common in vegetarians than nonvegetarians [22]. Of related interest, a low-fiber diet may be a common etiological factor in the development of both diverticulosis and colon cancer. In one report of 7000 patients, an excess number of colon and rectal cancers was noted in the first 2 years after diagnosis of diverticular disease [23], an incidence not explained solely by investigations performed for the evaluation of diverticular disease.

Other dietary factors have been examined. There is no substantially increased risk associated with smoking or caffeine or alcohol intake [24]. The recognized association of acute diverticulitis with obesity in men under 40 years of age may be associated with observations that a high intake of total fat or red meat plus a diet low in fiber particularly augments the risk of symptomatic diverticular disease [21]. Whether fat and red meat are independent risk factors or merely markers of a lower fiber diet remains speculative.

Pathophysiology

Pathology

The typical colonic diverticulum is a false or pulsion diverticulum; that is, it does not contain all layers of the wall, as is the case in a true (congenital) diverticulum. Mucosa and submucosa herniate through the muscle layer of the colon, separated from the intraperitoneal space only by the serosa. Diverticula develop at the four constant points of the colonic circumference where the vasa recta penetrate the circular muscle layer [25]. These vessels enter the wall of the colon on each side of the mesenteric taenia and on the mesenteric border of the two antimesenteric taeniae (Fig. 61.1). Diverticula do not develop in the rectum; presumably this is in some way related to the coalescence of taeniae into a longitudinal muscle layer.

Diverticula are distributed unevenly throughout the colon. In Western cultures, 95% of patients with diverticula have sigmoid diverticula. Diverticula are limited to the sigmoid colon in 65% of patients, whereas, in 24%, diverticula involve predominantly the sigmoid but with other segments of the colon involved to a lesser degree; in 7% of patients the distribution is equally divided throughout the colon, whereas in only 4% are diverticula limited to a segment proximal to the sigmoid [26]. Similarly, 95% of all operations for diverticular disease are directed at the sigmoid colon [7].

Pathophysiology of diverticular disease

Diverticulosis

The points at which diverticula develop, i.e., where the vasa recta penetrate the colon wall [27], are considered to be areas of potential weakness within the wall of the colon. Most patients with sigmoid diverticula exhibit grossly evident myochosis, that is, thickening of the circular muscle layer, shortening of the taeniae, and lumenal narrowing. Although there is no apparent hypertrophy or hyperplasia of the muscular layer of the colonic wall, there is increased deposition of elastin in the taeniae [28]. Structural changes in collagen

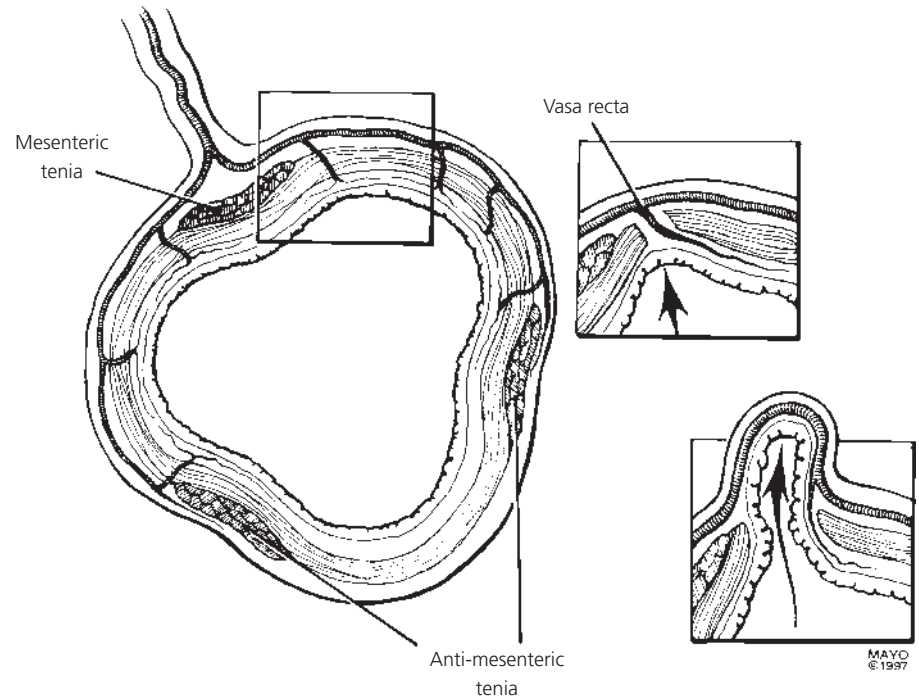

Figure 61.1 Cross-section of the sigmoid colon. content of the wall of the sigmoid colon are similar to those resulting from aging but are greater in magnitude [29] and may decrease the resistance of susceptible segments of the wall to abnormal increases in intralumenal pressure. Reduced levels of mature collagen type I and increased levels of collagen type III have been demonstrated in tissue from individuals with diverticulosis, in addition to reduced expression of matrix metalloproteinase-1 compared with normal controls [30]. Changes in the tissue collagen levels of patients with connective tissue disorders, such as the Ehlers–Danlos and Marfan syndromes, may explain the appearance of diverticula at an early age.

Application of the principles of the law of Laplace may explain, in part, the development of colonic diverticula. The law states that pressure (P) is proportional to wall tension (T) and inversely proportional to radius (R) of the colon – that is, $P = kT/R$ (where k is a conversion factor). Normally intralumenal pressure is the same throughout the colon. However, segmentation of the colon (a motility process in which proximal and distal segmental muscular contractions separate the lumen into isolated chambers) is believed to be exaggerated in diverticulosis. Strong occlusive contractions at both ends of the chamber lead to marked segmental increases in intralumenal pressures (Fig. 61.2) [31], which may predispose to herniation of mucosal diverticula at the sites where the blood vessels penetrate the muscular layers of the colon. Because the sigmoid colon is the segment of the colon with the smallest diameter, it may also be the site of the greatest intralumenal pressure. Whether the thickened taeniae of the sigmoid colon are a result of the environmental milieu, such as a lower fiber diet and less bulky stools (and a resultant less wide colonic diameter), a response to increased intralumenal pressure, a primary genetic variation in muscle structure and function, or an acquired abnormality from some other as yet undefined cause, remains unknown.

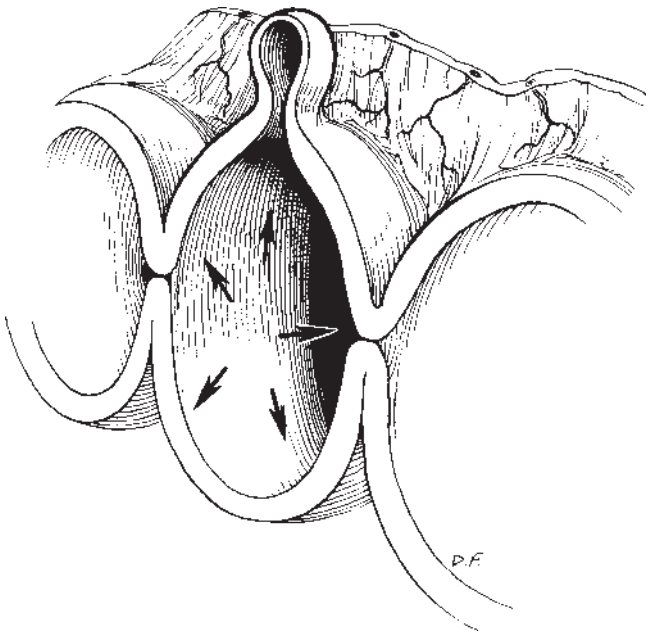

Figure 61.2 The concept of Painter and Burkitt of segmentation causing formation of pulsion diverticula.

The development of diverticula may result from disorders of both bowel-wall structure and motility. Golder and colleagues suggested a mechanism whereby structure and function may be tied together [32,33]. They described reduced smooth muscle choline acetyltransferase activity, up-regulation of M3 receptors, and increased in vitro sensitivity to acetylcholine in the sigmoid colon of patients with diverticulosis, i.e., the possibility of a cholinergic defect in diverticulosis. They postulated that increased expression of M3 receptors is a response to reduced cholinergic innervation and that this increased expression maintains normal tone, until there is external stimulation resulting in increased motility responses. Differential deposition of elastin in the taeniae may result in an inability of this layer to contract in response to acetylcholine, leading to uncoordinated contractions between circular and longitudinal muscle layers and the subsequent outpouching of diverticula.

Diverticulitis

Inflammation of the wall of the diverticulum and the surrounding peridiverticular tissue has a range of clinical manifestations from subclinical inflammation to generalized peritonitis. The underlying cause of the inflammation is thought to involve a micro- or macroscopic perforation of this thin-walled diverticulum. It was believed previously that obstruction of the ostia of the diverticula, for example, by fecoliths or lumenal material, led to increased intradiverticular pressure and subsequent perforation; this occurrence is thought to be rare [12]. Any physician who performs flexible sigmoidoscopy or colonoscopy routinely has seen numerous diverticula containing fecoliths – not one of which is inflamed. Increased intralumenal pressure in the involved segment of the colon secondary to abnormal motor activity or local trauma of inspissated fecoliths may erode the wall of the diverticulum. Inflammation and focal necrosis result in perforation. Frequently, a small perforation becomes walled off and contained by pericolic fat and mesentery, resulting in the formation of a localized abscess or resolution without further consequence. In contrast, with a more extensive inflammatory reaction, surrounding hollow organs adhere to the inflamed segment of colon, and intestinal obstruction or an internal fistula may develop. Poor containment, as may occur in antimesenteric diverticula, results in free intraperitoneal perforation and peritonitis.

In summary, diverticula occur at weakened points in the intraabdominal, taenia-bearing colon where intramural vessels penetrate the muscular layer. Development of diverticula appears to be multifactorial. Localized increases in intralumenal pressure may be caused by abnormal motor

patterns that predispose to exaggerated segmentation and are likely exacerbated by a low-fiber diet. Morphological changes in the muscle and collagen content of the bowel wall lead to decreased tensile strength of the wall; these changes are similar to, but more pronounced than, those that occur with age. Local trauma to the wall of the diverticulum may produce inflammation, resulting in either localized perforation with peridiverticulitis or free intraperitoneal perforation with generalized peritonitis. Similarly, local trauma to the vasa recti within the diverticula can predispose to hemorrhage.

Natural history

Understanding the natural history of diverticular disease is critical in determining which patients will develop complications if left untreated (and who are therefore appropriate candidates for operative intervention) and those who are best served by a more conservative approach.

Diverticulosis

Of patients with significant diverticulosis, 70% remain asymptomatic and never develop complications related to their diverticulosis. With long-term follow-up, however, as many as 15%–25% of patients with diverticulosis will develop acute diverticulitis and 5%–15% will exhibit diverticular bleeding (Fig. 61.3). As the majority of patients remain asymptomatic, the mere presence of multiple diverticula does not indicate the need for intervention other than possibly recommending a high-fiber diet in an attempt to decrease the incidence of complications.

Diverticulitis

Diverticulitis may present with manifestations ranging from mild abdominal discomfort to perforated diverticulitis with fecal peritonitis, sepsis, and even death. Diverticulitis can be divided into simple and complicated presentations (Fig. 61.4). Complicated diverticulitis describes localized or free intraperitoneal perforation, obstruction, abscess, or fistula, which arise in 25% of patients with their first episode of acute diverticulitis; nearly all of these patients will eventually require operative treatment. Simple diverticulitis accounts for 75% of episodes and refers to inflammation alone in the absence of complications; the majority of these patients respond rapidly to medical therapy.

Of those who require operative intervention, uncomplicated diverticulitis is the indication in approximately 40%, and the various manifestations of complicated diverticulitis account for the other 60% [6]. In a study of 934 patients hospitalized between 1988 and 1998 at a single medical center with proven diverticular disease requiring operative resection, the following were the indications for operative intervention: chronic diverticulitis 35%, perforation 18%, fistulae 16%, abscess 8%, obstructive symptoms 6.5%, stricture 6%, massive rectal bleeding 5%, and acute diverticulitis 4% [6].

Simple diverticulitis

Most patients with simple diverticulitis are initially treated conservatively (see Fig. 61.4); 85% respond rapidly, but 15% will require operative intervention [34]. Long-term follow-up of patients after their first episode of acute diverticulitis suggests a readmission rate of 2% per patient year [34] so elective colectomy is not necessary for all patients who respond to medical therapy. Indeed, after successful conservative therapy of the first attack of diverticulitis, 30%–40% of patients remain asymptomatic, 30%–40% have episodic abdominal cramps without frank diverticulitis, and about one-third proceed to a second attack of acute diverticulitis [4].

Older data suggest that the prognosis is worse with a second attack, because the rate of complicated diverticulitis

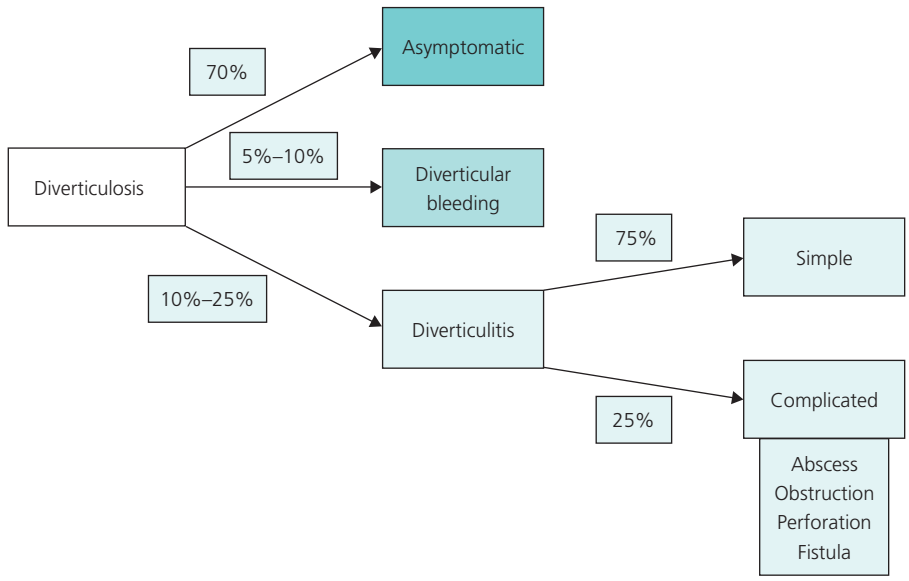

Figure 61.3 The natural history of diverticulosis. From Young-Fadok & Pemberton [149].

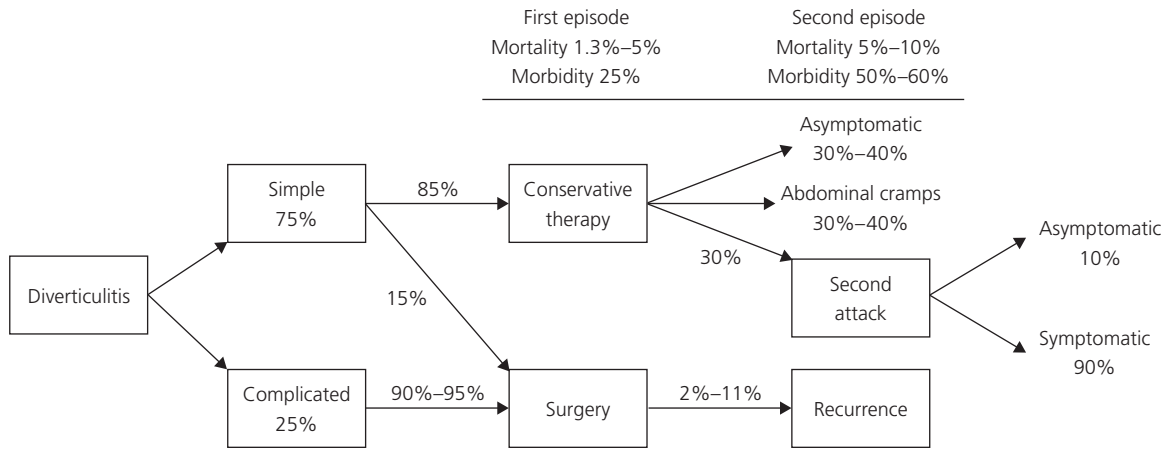

Figure 61.4 The natural history of diverticulitis. From Young-Fadok & Pemberton [149].

approached 60%, and the mortality rate doubled [4,35]. Only 10% of these patients remained asymptomatic after nonoperative resolution of a second attack of acute diverticulitis. These older studies form the basis for the current recommendation that resection should be recommended after two confirmed attacks of diverticulitis, with one episode of sufficient severity to merit hospitalization. This dogma has been challenged. Chautems and colleagues reported on 110 patients treated conservatively for a first episode of diverticulitis; 83 had complete follow-up, and 15 patients (18.3%) had one recurrence and only six (7.3%) had two or more episodes of recurrence [36]. Nine of these patients required inpatient therapy. Two patients underwent operation, and no emergency procedure was required. The authors concluded that recurrent diverticulitis may be treated in a similar fashion to a first episode and that medical therapy remains a valuable alternative to resection. This study was useful in having long median follow-up of 10.5 years, but the conclusions were hampered by a high death rate of 33.7% from unrelated causes during follow-up. Anaya and colleagues employed a statewide database to identify all patients hospitalized nonelectively for diverticulitis [37]. A total of 25 058 patients were hospitalized with an initial attack of diverticulitis. Of 20 136 not requiring initial operation, 19% had recurrences. Patients younger than 50 years were more likely to have a recurrent attack (27% vs 17%). Young age and increasing number of recurrent events were associated with the risk of emergency colectomy or colostomy after initial successful nonoperative treatment. Similarly, a study of 3165 patients confirmed that after nonoperative management of an initial episode the recurrence rate was only 13%, and age less than 50 years and a first recurrence were factors that predicted further recurrence [38].

Complicated diverticulitis

Most patients with complicated diverticulitis require operative intervention (Fig. 61.4). With the first attack of acute diverticulitis, 15%–29% require operative treatment [34,39], most of whom have complicated diverticulitis. The mortality rate is 1.3%–5% [34]. Indications for emergency or early operative intervention are generalized peritonitis, nonresolving intestinal obstruction, abscess that is not amenable to radiologically guided percutaneous drainage, clinical deterioration, or failure to improve with appropriate conservative management (Table 61.1). Indications for elective operative intervention are recurrent or intractable symptoms, persistent mass, inability to exclude carcinoma, functional colonic obstruction, presence of a fistula, and previous percutaneous drainage of an abscess. Several unique situations are discussed below.

Those who are treated operatively are generally thought of as cured even though the standard extent of resection may leave diverticula in the remaining proximal colon. Diverticulosis progresses in the remaining colon in about 15% of patients [40], and future operative treatment is required in as many as 2%–11% [40–42]. Up to 27% of patients after a colectomy may describe abdominal pain postoperatively in the same location; these persistent symptoms, however, may be secondary to coexistent irritable bowel syndrome rather than to recurrent diverticulitis.

Table 61.1 Indications for operative treatment of acute diverticulitis

Absolute	Relative
Complications of diverticulitis	Symptomatic stricture
Peritonitis	Immunosuppression
Abscess (failed percutaneous drainage)	Right-sided diverticulitis
Fistula	? Young patient
Obstruction	
Clinical deterioration/failure to improve	
Recurrent episodes	
Intractable symptoms	
Inability to exclude carcinoma	

Diverticular diseases

Diverticulosis

Diverticulosis in the majority of patients is asymptomatic. Some patients with uncomplicated diverticulosis have symptoms of cramping, bloating, flatulence, and irregular defecation; it is unclear if these symptoms are related directly to the underlying diverticulosis or to the coexistence of irritable bowel disease. Older patients with this symptom complex are investigated with a contrast enema, and the prevalence of diverticulosis in the elderly is so common that this ostensible association of symptoms and diverticulosis has often been made, but a true causal relationship is unproven.

Diverticulitis

Presenting symptoms

Constant, noncolicky, left lower quadrant pain is the most common complaint occurring in 70% of patients. The pain has often been present for several days before presentation, which helps to differentiate diverticulitis from other causes of an acute abdomen; only 17% of patients have symptoms for less than 24 h [7]. When carefully questioned, almost half the patients describe previous episodes of similar, although less intense, pain. Nausea and vomiting occur in 20%–62%, diarrhea coexists in one-fourth to one-third of patients [43], and recent obstipation has been present in one-half. Urinary symptoms, such as dysuria, urgency, and frequency, coexist in 10%–15%.

Presenting signs

Physical examination reveals abdominal tenderness, usually in the left lower quadrant. A tender mass is palpable in 20% [4]. Right lower quadrant tenderness may result from a redundant inflamed sigmoid colon lying to the right of the midline or, less frequently, from right colonic diverticulitis. Generalized peritoneal signs suggest free perforation and peritonitis. Abdominal distention occurs in two-thirds of patients. Low-grade fever and mild leukocytosis are common but not always present; 14% of patients have no fever, and 45% have a normal white count [44]. Urinalysis may reveal a sterile pyuria apparently secondary to adjacent inflammation; mixed colonic flora, fecaluria, or pneumaturia are pathognomonic of a colovesical fistula. Similarly, fecal discharge from the vagina is strongly suggestive of a colovaginal fistula.

Diagnosis

The diagnosis of diverticulitis should be suspected and made primarily on the basis of the history and physical examination. In the acute stage, when complicated diverticulitis is suspected, imaging studies can confirm the diagnosis and exclude other sources of acute abdominal signs; in contrast, elective evaluation after resolution of an acute episode of diverticulitis should evaluate the whole colon.

Diagnosis in the acute setting

Abdominal radiographs are useful and appropriate in excluding other causes of acute abdominal pain, rather than in making the diagnosis of diverticulitis. In addition, the presence of free air on the abdominal radiograph signifies an abdominal emergency and obligates further evaluation. The diagnosis of acute diverticulitis can be made frequently on the basis of the history and physical examination alone. Older published guidelines recommended that when the clinical picture was clear then additional tests were not necessary to make a diagnosis [45–47]. This may, however, have been a disservice to the patient. A clinical diagnosis alone may be incorrect in up to one-third of patients [48]. In addition, should there be additional unconfirmed attacks, the patient may potentially be put at risk when surgical management is refused, whereas had there been evidence of an earlier attack, an operative resection might have been prudent and the decision to proceed with resection would have been possible. In the patient who has symptoms of sufficient severity to merit hospitalization, our preference is to obtain radiographic confirmation with a computed tomography (CT) scan [49]. This is reinforced by more recent guidelines which suggest that CT of the abdomen and pelvis is usually the most appropriate imaging modality in the patient with suspected diverticulitis [50]. After an episode of uncomplicated acute diverticulitis, complete evaluation of the colon can be performed electively.

The immediate use of CT is not controversial if the diagnosis is not secure or if complicated acute diverticulitis is suspected. Computerized tomography has become the investigation of choice for diagnosis, recognition of complicated disease (abscess, fistula, obstruction), potential therapeutic intervention, and quantifying resolution of disease. Ambrosetti and colleagues performed a prospective comparison of CT and water-soluble contrast enema in 420 patients over an 11-year period [51]. Among 136 patients who subsequently underwent colonic resection, 132 had histologically proven diverticulitis. The CT was more sensitive than contrast enema (98% vs 92%) and identified all of those patients who had an associated abscess, whereas contrast enema only indicated indirect evidence of complicated diverticulitis in 29% of these patients. Helical CT with rectal contrast has been shown to have a sensitivity of 97% and specificity of 100%, similar to studies using oral contrast [52]. This technique may avoid the risks, discomfort, and costs of oral and intravenous contrast and allow for immediate scanning.

The CT features of acute diverticulitis (Fig. 61.5) include increased soft tissue density in pericolic fat secondary to inflammation in 98%, air-filled diverticula in 84%, bowel wall thickening in 70%, soft tissue masses representing a pericolic phlegmon, and pericolic (usually intramesenteric) fluid collections representing abscesses in 35% [53,54]. In 10% of patients, acute diverticulitis cannot be distinguished from carcinoma, as both may show focal thickening of the bowel wall; features more suggestive of acute diverticulitis

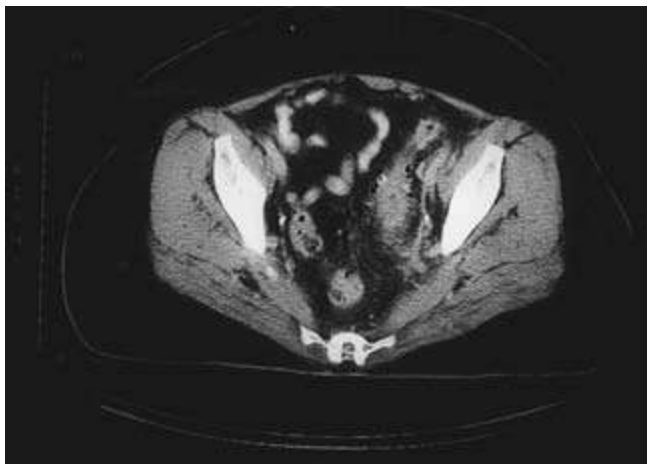

Figure 61.5 Computed tomography with oral and intravenous contrast in a 59-year-old woman with increasing abdominal pain for 3 weeks. Mild changes of diverticulitis are seen with narrowing of colonic lumen, bowel wall thickening in the midsigmoid, tissue stranding in pericolic pelvic fat, and diverticula. There is no pericolic fluid collection.

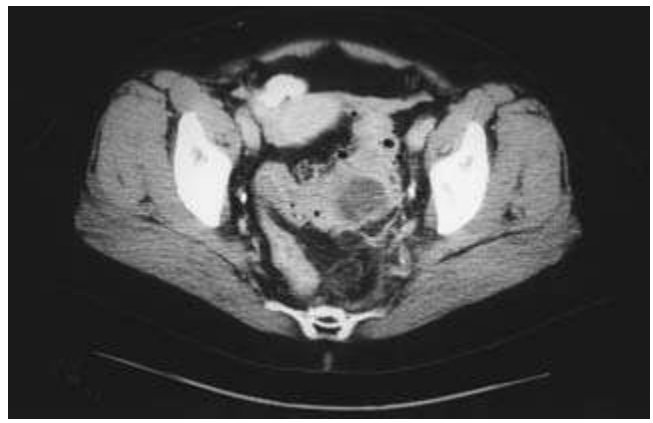

Figure 61.6 Computed tomography with oral and intravenous contrast in a 60-year-old woman with a 2-week history of crampy lower abdominal pain, fever, and chills showing a low-density mass adjacent to the sigmoid in the left pelvis. The central, low-density region within the mass, the pockets of surrounding gas, and inflammatory changes in pericolic tissues are consistent with diverticular disease.

are fluid at the base of the mesentery, edematous thickening of the mesentery, and mesenteric vascular engorgement [55]. Others have found additional features more suggestive of diverticulitis than carcinoma: presence of noninflamed diverticulum, inflamed diverticulum, mild degree of enhancement, and small lymph node size; when colonic obstruction is present colon cancer is more likely than diverticulitis [56]. A CT can identify complicated diverticulitis – i.e., peritonitis (diffuse inflammatory changes and scattered, loculated fluid collections), fistula formation (usually inferred from air or rectally administered contrast in bladder, vagina, or abdominal wall, rather than direct visualization of the fistulous tract), and obstruction. It correctly predicts Hinchey stage in more than 90% of cases [57], because it stages more clearly the extent of extralumenal inflammation, which is underestimated by contrast enema [51,54]. Findings on CT can be classified as mild disease (localized colonic wall thickening and inflammation of pericolic fat [see Fig. 61.5]) or severe (abscess, extralumenal air- or water-soluble contrast [Fig. 61.6]); the latter findings have been employed as criteria for elective resection in patients responding initially to medical therapy with resolution of acute clinical symptoms [58]. In addition, CT functions as a therapeutic modality when combined with percutaneous drainage of localized abscesses in selected patients; this approach avoids the need for emergent operative intervention and permits an elective, single-stage resection [59]. Computed tomographic colonography may also indicate the presence of the characteristic muscular thickening of the bowel wall associated with diverticulosis, and also demonstrates significantly less sigmoid colon distensibility compared with normal colons [60].

Contrast radiography or colonoscopy generally should be avoided in patients with suspected acute diverticulitis because of concerns that overzealous infusion of even water-soluble contrast or insufflation of air may lead to rupture of previously contained diverticulitis. However, a single-contrast enema using water-soluble contrast is safe in the acute phase if performed carefully. Pneumoperitoneum or evidence of generalized peritonitis should be absolute contraindications to the use of barium as the contrast agent [61]. Some physicians prefer a water-soluble contrast enema, even in the absence of these findings, in any patient suspected of having acute diverticulitis in the event that there is an unsuspected leak (Fig. 61.7). Contrast enema has the advantage of evaluating the colonic lumen, is less expensive and more readily available than CT, and in some practices is the initial procedure of choice; in the patient in whom the diagnosis of uncomplicated acute diverticulitis is secure, however, contrast enema examination adds little therapeutically useful information.

Magnetic resonance colonography may offer an alternative means of diagnosis. Features suggestive of diverticulitis are increased wall thickness, focal uptake of contrast material, and pericolonic reaction including mesenteric infiltration on T1-weighted images [62]. It has been found to be equally helpful in establishing the diagnosis of right-sided diverticulitis and may be a valuable alternative to CT in young or pregnant patients [63].

High-resolution, graded-compression ultrasonography may offer an innovative method to evaluate acute diverticulitis in experienced hands. Visualization of an abnormal colonic segment, as evidenced by mural thickening greater than

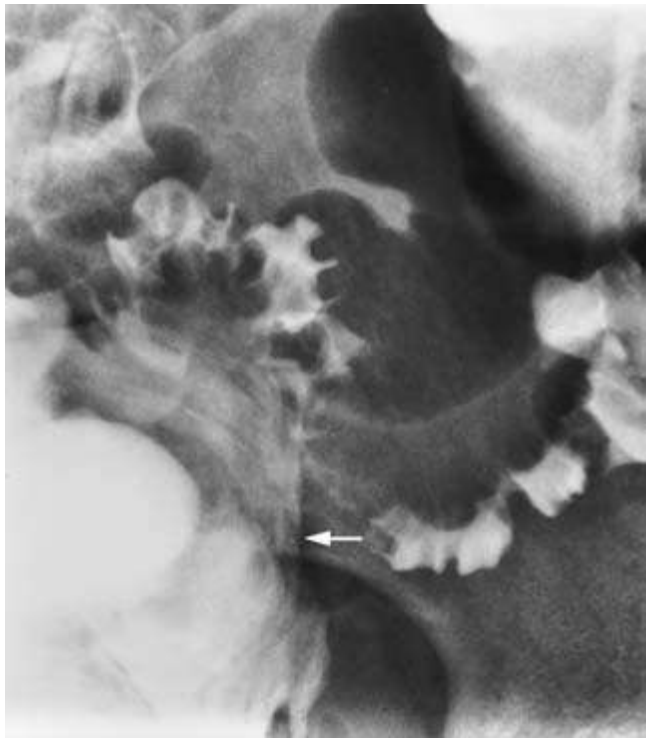

Figure 61.7 Hypaque enema in a 79-year-old woman shows nonanatomic distribution of contrast (*arrow*) around the rectum, demonstrating perforation.

4 mm and involving a segment 5 cm or longer at the point of maximal tenderness, is found in 85% of patients and represents the most specific sonographic feature [64]. In cross-section, the thickened colon has the appearance of a target (Fig. 61.8). Inflamed diverticula, mural abscess, extraluminal gas bubbles, peridiverticular abscess, and inflammation may be visualized. Reported sensitivities of ultrasonography range from 85% to 98%, with specificities of 80%–98% [64,65], but these values are undoubtedly operator dependent. Although ultrasonography is less widely accepted and validated in the evaluation of diverticulitis than CT, it may be a useful additional tool – for instance in following the resolution of an abscess, or in allowing percutaneous, transrectal, or transvaginal drainage of an abscess.

Diagnosis in the elective setting

After resolution of acute diverticulitis, evaluation requires imaging of the entire colon to determine the extent of disease and to rule out coexistent lesions, such as polyps or carcinoma. Pancolonic imaging may be achieved with colonoscopy or flexible sigmoidoscopy plus barium enema. An investigational method being developed, virtual colonoscopy (also colography or colonography) (Fig. 61.9), may prove to be useful in the elective setting. This technique employs air insufflation of the colon and rapidly acquired CT images, which allow computer generation of a three-dimensional image of the colonic lumen. On occasion, diverticulitis may lead to stricture formation with the characteristic appearances of carcinoma; this finding requires further intervention as for suspected colon cancer.

Treatment

Decision to observe or operate

Treatment must be individualized for each patient; correct initial therapy depends on clinical acumen (see Table 61.1). The spectrum of disease can be divided into mild symptoms,

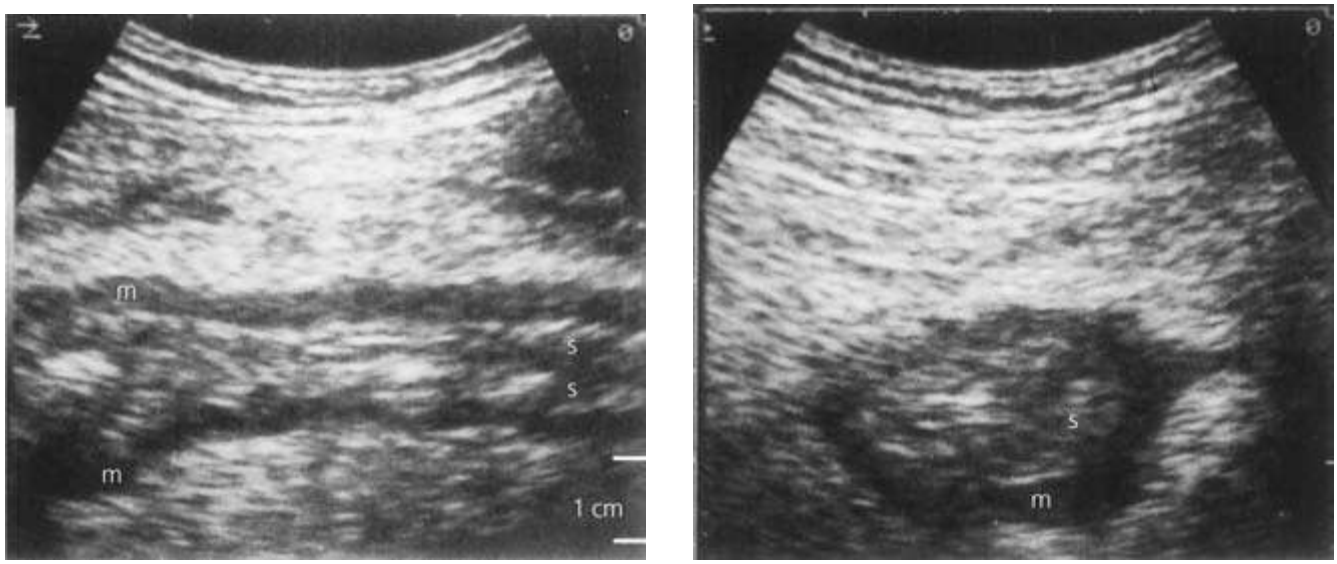

Figure 61.8 Ultrasonographic findings of sigmoid diverticulitis. Figure 61.10 Algorithm for treatment of acute diverticulitis.

moderate to severe symptoms, and diffuse peritonitis (Fig. 61.10). The first and last groups require little decision-making regarding operative intervention; the second group is the more challenging.

Mild symptoms

Patients with mild diverticulitis are characterized by left lower quadrant pain, low-grade fever, and minimal physical findings without peritonitis. These patients are best treated as outpatients with a liquid diet and broad-spectrum oral antibiotics such as ciprofloxacin or metronidazole. Exceptions include immunosuppressed patients and other high-risk groups, such as patients with diabetes or the elderly. Patients can be followed for increasing fever, pain, or inability to tolerate oral intake. Hospitalization is only necessary if the patient fails to improve. Diet is reintroduced as symptoms resolve. Once the episode has resolved, the colon should be evaluated, usually 6 weeks later to allow residual inflammation to resolve. After symptoms have resolved, long-term therapy with fiber is generally recommended as one of the few interventions that may alter the risk of recurrence. There has also been some interest in the use of mesalazine to reduce the risk of recurrent symptoms. One study, using a scoring system that included such variables as abdominal pain, bloating, tenesmus, diarrhea, tenderness, and fever, found that mesalazine reduced symptoms at 3 months follow-up

compared with rifaximin [66]. A randomized trial from Italy comparing long-term use of rifaximin alone with rifaximin plus mesalazine, found that the latter combination was more effective in producing resolution of symptoms and prevention of recurrent episodes [67]. Another interesting randomized study has indicated that administration of an oral immunostimulant, a highly purified, polymicrobial lysate, to patients with at least two attacks of diverticulitis was effective compared with placebo in reducing the risk of recurrent attacks [68]. The combination of mesalazine and *Lactobacillus casei* has been shown in a randomized trial to be effective in preventing recurrence of symptomatic uncomplicated diverticulitis [69].

Moderate to severe symptoms

This patient group can be distinguished by the presence of more severe, left-sided abdominal pain, fever, chills, obstipation, and left lower quadrant peritoneal irritation. Classic symptoms do not initially require advanced diagnostic imaging, and medical therapy is instituted on the basis of a clinical diagnosis [70]. When the diagnosis or extent of disease is in doubt, CT or water-soluble contrast enema should then be considered. In stable, immunocompetent patients, initial treatment is conservative with bowel rest, intravenous fluids, and broad-spectrum parenteral antibiotics. Antibiotics need to be active against gram-negative rods and anaerobes; a single antibiotic active against both aerobes and anaerobes appears to be as effective as combination therapy, for example, a second-generation or third-generation cephalosporin, or an aminoglycoside combined with an anaerobically active agent such as metronidazole or clindamycin [47,71,72]. The aim is to obtain a clinical response to avoid the need for early, nonelective operative intervention. Except for patients with generalized peritonitis, this approach is usually successful. A CT may help to identify patients who are likely to respond to medical therapy [59,73].

Three outcomes are possible: improvement, failure to improve, or deterioration. Clear improvement should occur within 24–48 h, with a decrease in pain, fever, tenderness, and leukocytosis [7,12,74]. Oral intake can be resumed once abdominal tenderness has resolved. Workup is completed 2–6 weeks after the acute phase has settled either with colonoscopy or flexible sigmoidoscopy combined with barium enema. Fiber supplementation of the diet may prevent recurrence in 70% of patients [74].

If there is no objective improvement, the diagnosis may be incorrect or complicated diverticulitis is present. A CT should be obtained. Abscesses amenable to treatment should be drained percutaneously at the time of the CT. Operative intervention is necessary if there is no reversible condition, if abscesses cannot be drained, or if drainage does not result in improvement. If a patient's condition deteriorates and there is no treatable condition visible on CT, operative exploration should proceed without waiting.

Peritonitis

Diffuse peritonitis mandates initial resuscitation, broad-spectrum parenteral antibiotics, and operative intervention; diagnostic studies are rarely necessary. Perforated diverticulitis is a serious disease carrying a mortality rate of 6% for purulent peritonitis and 35% for fecal peritonitis [75].

Which operation – surgical principles

The surgeon's aims are to remove the septic focus by resecting the involved segment of colon, to treat the associated obstruction or fistula, and, if possible, to restore bowel continuity, while minimizing morbidity and mortality.

Preoperative preparation

In nonemergency situations, mechanical bowel preparation with or without oral antibiotics is usually possible and may decrease the rate of wound infection. Patients should be warned of the possibility of a stoma and the abdomen should be marked for optimal stoma placement preoperatively, taking into consideration body habitus, belt line, and so forth. Preoperatively placed ureteral stents are usually unnecessary but may be helpful if there is intense pericolonic inflammation. Positioning the patient in a modified lithotomy position allows a circular stapler to be passed transanally if anastomosis is possible; this positioning also allows intraoperative proctoscopy to assess and empty the rectum if necessary.

Intraoperative assessment

Under emergency conditions, the abdomen is explored through a midline incision; a laparoscopic approach may be possible electively at least 6 weeks after the episode of diverticulitis has resolved. Assessment of peritoneal contamination, proximal obstruction, and fecal load determine the advisability of a primary anastomosis (Hinchey's classification; Table 61.2) [76]. For instance, class I and II disease may still allow a primary anastomosis, depending on whether the abscess is removed en bloc with the resected segment (as with an intramesenteric abscess), or whether the abscess has been well-controlled by the peritoneum, can be safely drained without local contamination, and is distant from the anastomotic site.

Table 61.2 Hinchey's classification of diverticulitis

Stage	Characteristics
I	Pericolic or mesenteric abscess
II	Walled-off pelvic abscess
III	Generalized purulent peritonitis
IV	Generalized fecal peritonitis

Adapted from Rao et al. [52].

In elective or semielective situations, resection and primary anastomosis are usually possible because the inflammatory condition is well localized or has resolved substantially. After resection, the ends of the bowel for anastomosis must be well vascularized, nonedematous, and tension free. The distal margin of resection should be in the upper third of the rectum, because there are no diverticula distal to this point. A multivariate analysis of factors involved potentially in recurrent diverticulitis after prior sigmoid resection indicated that the level of the anastomosis was the single predictor of recurrence. Patients with a colosigmoid anastomosis had a four times higher risk of having a recurrence than patients with a colorectal anastomosis [77]. The proximal resection should extend to where the colon becomes soft and nonedematous. It is not absolutely necessary to remove all diverticula-bearing colon proximal to the intended anastomosis [42], but attempts should be made to remove the majority of diverticula on the left side of the colon. Absolute contraindications to primary anastomosis are fecal or purulent peritonitis; relative contraindications include severe comorbid conditions that might jeopardize blood flow, poor nutrition, and immunosuppression [69].

In emergency situations with peritoneal contamination, a two-stage procedure is appropriate (Fig. 61.11). The most common two-stage approach involves resection of the diseased colon, oversewing of the rectal stump, and an end colostomy – a Hartmann procedure. In patients with fecal or purulent peritonitis, this approach is the preferred method. Creation of a mucous fistula from the rectal stump is not possible after resection of the entire sigmoid. Many surgeons mark the rectal stump with a long, nonabsorbable suture and tack it to the anterior abdominal wall or sacral promontory for ease of location in the future. The colostomy can be closed 3 months later. Cleveland Clinic has developed a propensity score that incorporates independent predictors of the decision to proceed with Hartmann resection: body mass index at least 30, Mannheim peritonitis index more than 10, operative urgency (emergent, urgent vs elective), and Hinchey stage [78].

The Hartmann procedure removes the source of sepsis, but reversal of the colostomy is often difficult because of adhesions and difficulty identifying the rectal stump [7,12]. Up to one-third of patients are left with a permanent stoma [79], and this percentage has remained surprisingly stable over the last 10 years. Of 11 582 admissions for diverticulitis in California over a 1-year period, 1176 underwent a Hartmann procedure, and over 35% had not had the colostomies reversed at 4-year follow-up [80]. Those patients who do undergo reversal have a higher rate of postoperative complications than patients undergoing primary resection and anastomosis (53% vs 31%) [81]. Relative contraindications to an unprotected anastomosis include the presence of a chronic abscess cavity and mild systemic illness, in which case the patient may be better served by creation of a protected

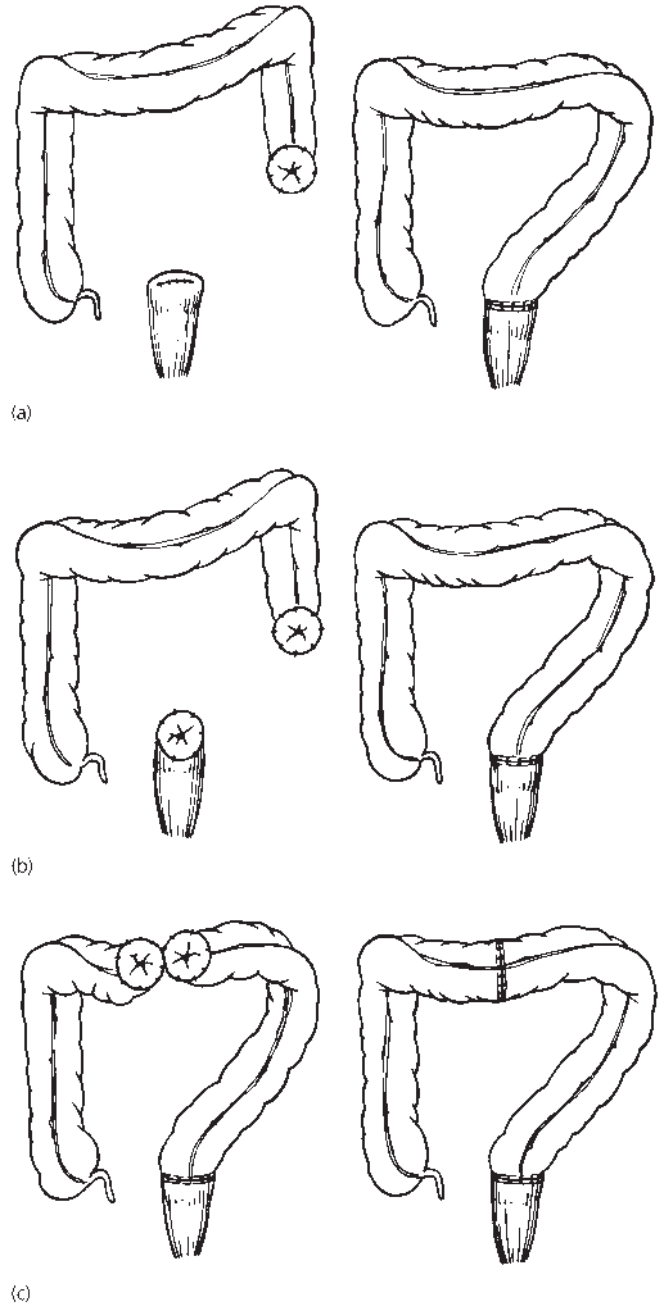

Figure 61.11 Two-stage approaches to resection of diverticular disease. Common among the approaches is that the offending segment of diverticular disease is resected at the first operation. **(a)** Stage 1: The Hartmann procedure. Diseased sigmoid colon is removed, the fecal stream is diverted, and the rectum is oversewn. Stage 2: Intestinal continuity is reestablished by a descending colorectostomy. **(b)** Stage 1: Diseased sigmoid colon is removed and both ends of bowel are brought to the surface, one as an end colostomy and the other as a mucous fistula. Stage 2: Intestinal continuity is reestablished as in **(a)**. **(c)** Stage 1: Diseased sigmoid colon is resected and a colorectostomy is constructed and protected by a diverting transverse colostomy or diverting loop ileostomy. Stage 2: Closure of the transverse colostomy is achieved.

primary anastomosis. This increasingly popular two-stage approach entails resection, primary anastomosis, and proximal diverting stoma; the second stage then involves a simple stoma closure. This approach is employed when there are relative contraindications to primary anastomosis, but no purulent or fecal peritonitis, and the bowel is nonedematous. This option has advantages because the second-stage stoma closure may often be accomplished through the stoma site alone, especially if a diverting loop ileostomy (our preference) is used. Another factor in the emergent setting is that bowel preparation is not possible, and a large fecal load precludes a primary anastomosis. Consideration may be given to intraoperative lavage in selected patients to permit primary resection and anastomosis. In addition to mobilization of the affected sigmoid, mobilization of the splenic and sometimes the hepatic flexure may help [49]. Bowel proximal to the sigmoid is occluded with tape, and immediately above this, the lumen is cannulated with large-bore, corrugated plastic tubing (anesthesia ventilator tubing). The end of the tube is passed off the field. The distal cecum, or appendix base, is cannulated with a Foley catheter through which warm saline is infused until the efflux is clear. Lavage was performed in 33 of 62 patients undergoing nonelective operation for diverticulitis: 18 Hinchey stage I, 10 stage II, and five stage III disease [82]. Only one anastomotic complication occurred.

The outdated classic three-stage procedure (Fig. 61.12) is no longer indicated [70] because it has a mortality rate of 26% vs 7% after a two-stage resection [75]. In rare and exceptional cases, if mesenteric inflammation precludes a safe dissection of the involved segment from the iliac vessels and ureters, or if the patient is unstable, it may be necessary simply to drain the area and create a proximal stoma. Rarely, optimal patient care in areas lacking a well-qualified abdominal surgeon is best served by drainage and diversion, which allows stabilization and early transfer to a large center for definitive therapy.

Laparoscopic vs open approaches

Laparoscopic techniques may be valuable in several facets of diverticular disease [83]. These include diagnosis, diversion, resection of the affected segment of colon, and restoration of colonic continuity (either as a staged procedure or primarily). Absolute contraindications to the laparoscopic approach are free perforation with fecal peritonitis or extensive purulent peritonitis because of the limitations on complete exploration and clearance of contaminated material. Both single institution [84–86] and multicenter [87] studies have demonstrated benefits of this approach in terms of reduced ileus and hospital stay, with similar or even reduced [88] complication rates compared with laparotomy. This approach can be achieved with reduced total direct costs for the laparoscopic cases [89]. Laparoscopic techniques can adhere to the same principles as open operations, with the ability to construct the anastomosis at the equivalent level in the rectum, resulting in no differences in rates of recurrent attacks of diverticulitis, although the latter may be biased by fewer follow-up periods in the laparoscopic group [90]. Hand-assisted vs pure laparoscopic techniques may offer shorter operative times and lesser conversion rates, although most studies are biased by selection based on time period (the hand-assisted device being utilized in more recent cases) or perceived difficulty of the case resulting in the decision to use a hand-assisted approach [91]. Randomized trials confirming superiority of the approach, however, have not been performed.

The inflammation that may accompany diverticulitis is often challenging even in open procedures. Resolution of the

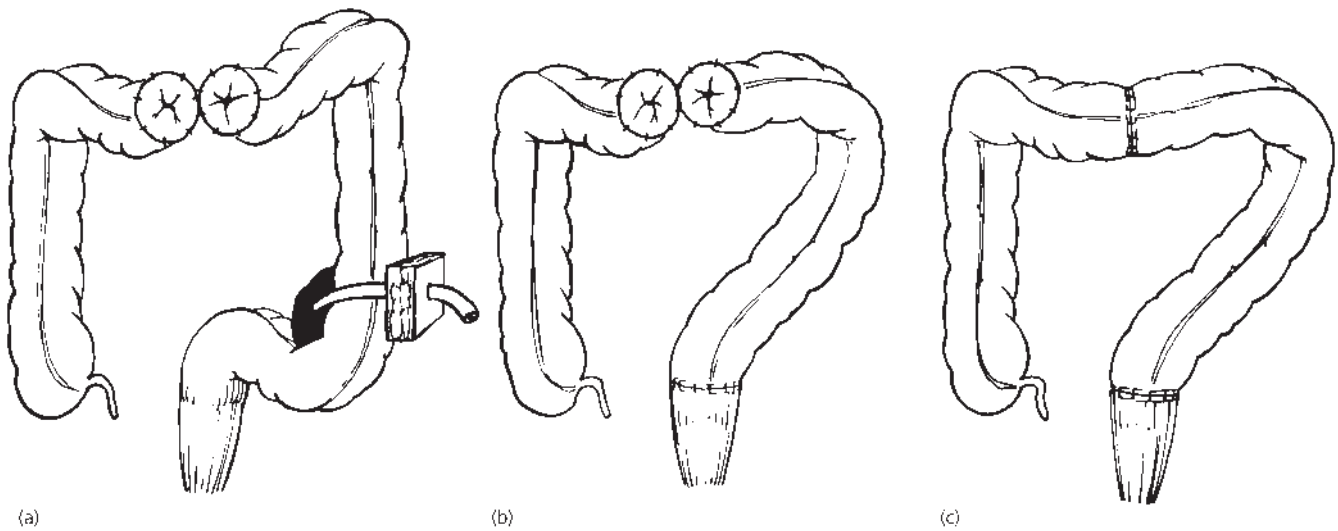

Figure 61.12 Three-stage resection of diverticular disease. **(a)** Stage 1: Diverticular abscess is drained and the fecal stream is diverted by a double-barreled colostomy. **(b)** Stage 2: Sigmoid diverticular disease is resected and a colorectostomy is constructed. **(c)** Stage 3: The colostomy is closed to restore intestinal continuity.

inflammatory component permits a successful laparoscopic approach in most cases [83]. The presence of a colovesical, colovaginal, or coloenteric fistula reduces the chances of completing the procedure laparoscopically, as does previous use of a drain, but is not an absolute contraindication to this approach. Even in open cases, the bladder side of a colovesical fistula frequently requires nothing more than pinching off the fibrous fistula track and leaving the bladder decompressed with catheter drainage, and the same principles apply to the laparoscopic approach. Ureteral stents may be helpful, and the firm tubular structure of the stent in the retroperitoneum can usually be detected with the laparoscopic instruments, making lighted stents unnecessary. As with open procedures, it is helpful to approach the mass in the sigmoid from both cephalad and caudad directions having identified normal tissue planes away from the phlegmon. Substantial experience is required to identify these planes. A low threshold for conversion to laparotomy should be maintained to avoid damage to vessels and ureter. The same extent of resection should be accomplished laparoscopically as for an open procedure, namely proximal resection of the sigmoid back to soft, pliable tissue, and distal resection to a point where the taenia have coalesced, usually to a point below the sacral promontory. This precludes an extracorporeal anastomosis and mandates an intracorporeal stapled anastomosis. One study of 79 laparoscopic sigmoid resections vs 79 open procedures, showed lesser rates of splenic flexure mobilization in the laparoscopic group (19% vs 41%) but also lesser rates of finding taeniae coli at the resection margin (4% vs 53%), suggesting a more distal anastomosis in the laparoscopic group [92]. With a minimum follow-up of 5 years in each group, there was no significant difference in the rate of recurrence (three vs seven patients). In patients who did have a recurrence, the rate of taeniae coli present at the distal resection margin was significantly increased, suggesting a potential advantage of the laparoscopic approach, which appeared to achieve a more distal margin.

Figure 61.13 Contrast enema revealing picket fence appearance of the sigmoid colon, associated with symptoms of obstruction.

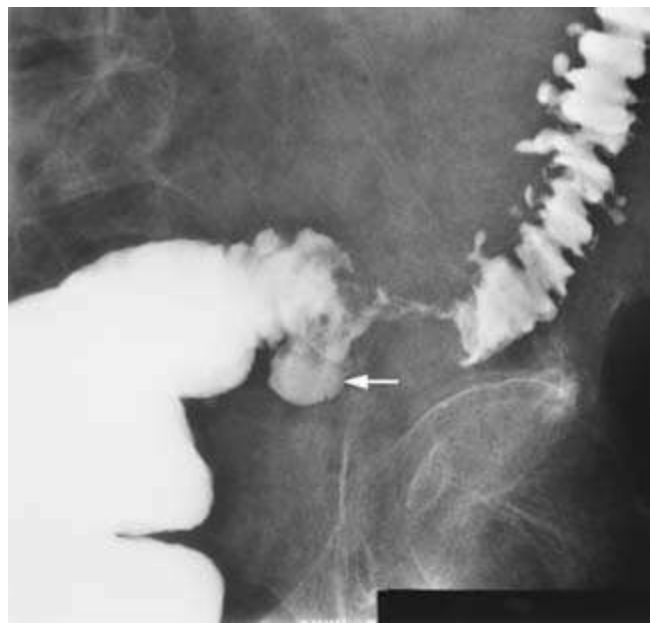

Figure 61.14 Barium enema demonstrating constricting lesion in sigmoid colon in a region of diverticulosis. There is also a 3-cm localized collection of barium (*arrow*) off the lateral colonic wall consistent with an abscess cavity. The most likely radiological diagnosis is diverticulitis but carcinoma cannot be excluded.

Complications

Obstruction

Diverticular obstruction of the colon is rarely a true or complete mechanical obstruction; however, obstipation as the result of functional obstruction is a common presenting complaint. Evaluation often shows a ratty stricture of the involved segment with a picket fence appearance (Fig. 61.13). The primary concern is differentiation from carcinoma (Fig. 61.14); even with negative biopsies, resection is usually unavoidable for this suspicious appearance. Resection with primary anastomosis is often possible, with colostomy if the preoperative bowel preparation is inadequate. In rare situations, acute diverticulitis leads to complete mechanical large bowel obstruction; this situation requires an emergent exploration. The inflammatory reaction may also involve secondarily the small bowel, leading to a small bowel obstruction; if this fails

to respond to nonoperative treatment, operative intervention may be necessary.

Perforation

Free intraperitoneal rupture of diverticulitis is unusual but is associated with extremely high mortality rates of 20%–30% [75,93] and appears to be more common in severely ill or immunocompromised patients. Treatment involves an emergent, two-stage procedure with resection of the involved segment and proximal diversion.

Abscess

Abscesses occur in 16% of patients with acute diverticulitis presenting without peritonitis [58] and in 31%–56% of patients requiring early operative intervention for diverticulitis [7]. Before the introduction of radiologically guided, percutaneous techniques of drainage, abscesses mandated operative intervention, often requiring a two-stage procedure. Percutaneous drainage permits a future, elective, single-stage operative approach in 60%–80% of patients [94–96]; indeed, in selected patients with severe comorbid conditions, which contraindicate operative therapy, catheter drainage alone may relieve symptoms and provide definitive treatment [95]. The catheter should remain in place until drainage is less than 10 mL in 24 h; this approach may take up to 30 days [95]. Contrast radiographs through the drainage catheter (sinograms) can show persistent communication between the bowel and the abscess cavity and may be one way to follow resolution of the abscess. The route of drainage is preferably through the anterior abdominal wall; abscesses deep in the pelvis or obscured by other organs may be accessed transgluteally or through the rectum or vagina [97,98], but these approaches are less optimal for patient comfort and catheter care. Operative intervention is indicated if improvement does not occur.

Fistula

Incidence

Fistulae account for up to 20% of all indications for operative intervention in complicated diverticular disease [99]. Because 90% of diverticular inflammation involves the sigmoid colon, fistulization most commonly arises from this segment. Colovesical fistulae (Fig. 61.15) comprise 65% of diverticular fistulae, colovaginal fistulae comprise 25%, and coloenteric and colouterine fistulae are less common [99], but fistulae can form with any hollow organ and they have been described in many unexpected sites (Fig. 61.16).

Colovesical fistulae are the most common form of diverticular fistula and, conversely, diverticulitis is the commonest cause of colovesical fistula, accounting for 40%–89% [100]. Although acute diverticulitis has an overall slight female predominance, males comprise the majority (66%–78%) of patients with colovesical fistulae secondary to diverticulitis [99,101]. The uterus appears to protect the bladder from the inflamed sigmoid; indeed, 50%–68% of women with colovesical fistulae and 83% of with colovaginal fistulae have had a previous hysterectomy [99,100,102].

Figure 61.15 Barium enema in a 54-year-old woman with pneumaturia and left lower quadrant pain. A fistulous tract (*closed arrow*) arises in the mid sigmoid passing into an abscess cavity (*arrowhead*) and then into the bladder, where contrast is also seen (*open arrow*). From Young-Fadok & Pemberton [149].

Clinical features and diagnosis

Colovesical fistulae are illustrative of most forms of diverticular fistulae. Only about 50% of patients will give a history of diverticulitis; in the remainder, diverticulosis is diagnosed when the fistula manifests clinically [101]. Patients describe passage of feculent matter or gas during urination; this manifests as pneumaturia in 67%–75%, dysuria in 56%–94%, or fecaluria in 50%–76% [99–101]. Crampy abdominal pain, diarrhea, hematuria, and passage of urine per rectum occur in a much lower percentage of patients [99,101]. Physical examination is characteristically unremarkable. Urinalysis is invariably abnormal with pyuria or fecal particulate matter; cultures reveal a polymicrobial growth. Such findings suggest a fistula, but not the etiology, which may be diverticulitis, Crohn's colitis, or carcinoma.

Computed tomography, barium enema, colonoscopy, cystoscopy, cystogram, and intravenous urography have all been used for the diagnosis of colovesical fistula. The reported

Figure 61.16 Barium enema in a 64-year-old man with 3 weeks of right hip pain. There is extravasation of barium from a perforated sigmoid diverticulum with collection of contrast material in an abscess cavity (*white arrow*) adjacent to the diverticulum. A fistulous communication extends from the abscess cavity to the right lower quadrant and extends to the region of the right hip (*black arrow*). From Young-Fadok & Pemberton [149].

diagnostic yield of each modality varies widely in different reports. The diagnostic yield from contrast enema and colonoscopy tends to be low (20%–26% and 0%–3%, respectively) [100,101], but these studies are valuable in assessing the proximal colon. Although the actual fistula is rarely demonstrated, abnormalities suggestive of the diagnosis are present in up to 100% of barium enemas and 25% of colonoscopies. If the diagnosis remains questionable after these studies, or if further anatomic delineation is required, CT is the most accurate and sensitive test. Occasionally, the fistula itself is opacified but, more commonly, colonic thickening adjacent to an area of thickened bladder, associated diverticula, and the presence of rectally administered contrast material or more commonly gas in the bladder (before instrumentation of the urinary tract) are present and are highly sensitive and specific for colovesical fistulae [103]. Gas bubbles within organs other than the bowel are highly suggestive of fistulization [53]. Although CT may not actually delineate the fistula tract, associated findings predict the location of the involved segment of colon and provide important information regarding extralumenal inflammation and its relationship to the ureters.

Cystoscopy, lauded by some authors, identifies directly only 20% of fistulae but strongly suggests the diagnosis by localizing inflammation and bullous edema of the bladder mucosa in the vast majority (96%) of patients [100]. Others consider such changes too nonspecific and find cystoscopy useful in only 37%–46% of patients [99,101]. Similarly, retrograde cystography and intravenous urography objectively demonstrate the fistula in less than 30% of patients and generally are of little clinical benefit.

Treatment

In general, diverticular fistulae do not close spontaneously, but also the presence of a fistula is rarely an indication in itself for urgent operative intervention; indeed, the rare instance of an acute initial presentation of a fistula may be an indication to postpone operative correction until the acute inflammation inducing the fistula resolves. As most patients present electively and can tolerate a bowel preparation, a one-stage procedure with resection and primary anastomosis is usually feasible and is associated with decreased morbidity and hospital stay [100]. If extensive inflammation is present and operative intervention is required to treat nonresolving acute diverticulitis, a two-stage procedure may be necessary.

The portion of the colon from which the fistula arises should be resected as described previously (see section on treatment). Management of the fistula site at the bladder depends on the size of the fistula, the degree of local inflammation, and the anatomic site. In most patients, the fistula can be pinched off, and either no visible defect in the bladder wall or a small defect will be evident. Management of the site of the fistula in the bladder may include merely leaving an indwelling bladder catheter for 7–10 days with or without closing the bladder defect with a few absorbable sutures over the site and leaving a closed suction drain in the region of the bladder defect. With a larger defect, simple closure is almost always preferred to formal resection, which is almost never necessary because the cause of the fistula originates in the colon and the bladder itself is normal; any local induration usually settles rapidly once the inciting cause (the colon) has been removed [69]. These simple principles of minimal intervention apply to the distal aspect of most types of diverticular fistula, be they in small bowel, vagina, or uterus.

Although operative management is usually recommended, in highly selected patients, especially with severe comorbid conditions, there may be a rationale for conservative nonoperative management, but no good follow-up studies are available to support this approach in most patients. In one series, six patients were managed nonoperatively for 3–14 years, treated only with prophylactic antibiotics; there were no complications and specifically no impairment of renal function and no urinary sepsis [104]. In the absence of urinary tract obstruction, observation appears safe in patients

with significant contraindications to operative management; this nonoperative approach may, however, be unacceptable if the symptoms are bothersome.

Special situations

Diverticulitis in the younger patient

Management of patients with their first episode of acute diverticulitis at less than 40 years of age is controversial. The current standard of therapy is to recommend resection after one episode based on two premises: first, these patients suffer a more virulent disease; and, second, patients responding to medical therapy are much more likely to have recurrent diverticulitis and ultimately require operative intervention. However, controversy exists as to the true virulence and natural history in this age group. Young patients comprise 12%–29% of the larger series of patients with acute diverticulitis requiring operative treatment [8,9,339,69,105]. Common findings are a male predominance of from 2 : 1 to 4 : 1 [8,9,39,69] and the coexistence of obesity in 84%–96% [9,69].

The concept that diverticulitis is more virulent in the young arises from follow-up studies of younger patients with their first episode of acute diverticulitis; 48%–88% of this group will require operative treatment either acutely or in the future [9,69,105]. Others describe much lower rates of operative intervention (15%–41%) and a more successful nonoperative management approach [8,39]. These inconsistencies may arise, because the younger patient may undergo operation because of an incorrect diagnosis [106]; some series have high rates of incorrect diagnoses approaching 50% [9,69]. This inordinately high rate is probably because the diagnosis of diverticulitis is not entertained in this young population, and the presence of localized peritonitis is interpreted as an abdominal catastrophe requiring emergent operative exploration. If CT or contrast studies are used more widely, then the operative rate in young patients is actually only 15% compared with as high as 33% in older patients [39]; however, the diagnosis of acute diverticulitis must first be entertained.

The natural history of acute diverticulitis in this young population after initially successful medical management is disputed. Some studies report readmission rates of 55% [107] and subsequent operative rates of 20%–41% [106–108]; others report no need for operation during a mean follow-up of more than 4 years [109]. When the total operative rates are examined with long-term follow-up, data are more consistent with an ultimate operative risk of about 50%. Some series have high initial operative rates [9,69,105], while others with a lower rate of acute operation (15%–25%) have higher rates at later times (29%–32%) [39,108]. In one study of 762 patients admitted with diverticulitis, 259 (34%) were younger than 50 years [110]. The risk of requiring operative intervention during the first hospitalization was similar between patients younger than 50 years and patients older than 50 years (24% vs 22%). However, although the younger patients were more likely to be treated operatively during the study period, this was because of an increase in elective resections, not further episodes of disease. These authors espoused a selective approach in young patients. This study differs from that of Chautems and colleagues who evaluated the long-term natural history of sigmoid diverticulitis in 144 patients treated nonoperatively for a first acute episode [111]. Young age and severe diverticulitis (by CT criteria) were both statistically significant factors of poor outcome (persistent or recurrent diverticulitis), but age was no longer significant after stratification for disease severity as graded on CT (but the analysis did suggest that more severe disease was linked to a younger age).

Although there are no reliable convincing arguments that mandate elective resection in this younger population after resolution of *uncomplicated* diverticulitis, in patients with no comorbid conditions, early elective colectomy after one episode of acute diverticulitis seems the most reasonable recommendation. It does seem clear, however, that the issue is one for individualized frank discussion with each patient to evaluate their risk and lifestyle concerns.

Immunocompromised patient

Pharmacological or functional immunosuppression is associated with an increased risk of severe diverticulitis. This patient group includes those patients treated with chemotherapy, corticosteroids, and medications such as azathioprine or cyclosporine, but the phenomenon is also apparent in diabetics and those with chronic renal failure. These patients may present with minimal symptoms and unimpressive abdominal findings even when they have advanced peritonitis; so the diagnosis is frequently delayed. In patients who have undergone heart or lung transplantation, the risk of severe diverticulitis requiring operative intervention has been estimated to be over 20 times greater than in the general population [112]. While aggressive medical therapy is successful in 75% of normal patients with acute diverticulitis, operative intervention is necessary in most immunocompromised patients [113]; early operative intervention must be entertained in these patients, especially if they fail to show an objective response early during aggressive medical treatment. Patients who respond to medical therapy should be considered for operative intervention after just a single episode and appear to tolerate operative intervention well [110]. Patients with connective tissue disorders, such as systemic lupus, appear to have an increased risk of complicated diverticulitis over and above that related to immunosuppression from use of steroids [114].

Right-sided diverticulitis

Right-sided diverticula comprise 5% of diverticulosis in Western countries [3] but up to 20% in Asia [13,14]. Most are wide-mouthed, false diverticula [16]. Patients tend to be younger than those with left-sided disease [13,14]. Because

right-sided acute diverticulitis presents clinically as acute appendicitis, the correct preoperative diagnosis is made in only 4%–16% of patients.

If an objective diagnosis can be secured preoperatively, then aggressive medical management should be undertaken. More commonly, the diagnosis is made or suspected only intraoperatively. If there is no peritoneal contamination, an obviously normal or absent appendix, and no worry of colonic malignancy, then appropriate management involves parenteral antibiotics and an appendectomy if the appendix is present [13,14]. If the diverticulitis is limited, consideration can be given to simple diverticulectomy [14] (and appendectomy). However, if there is diverticular perforation, extensive inflammation, or a colonic malignancy that cannot be confidently excluded, then some form of right colectomy is justified. Primary anastomosis is usually possible, but one should not hesitate to construct an ileostomy and distal mucous fistula in the presence of severe peritonitis or in the compromised host [13,17].

Diverticular bleeding

Incidence

Diverticular bleeding is the most common cause of acute massive colonic blood loss, accounting for 30%–50% of massive bleeding [115,116]; although angiodysplasia makes up an additional 20%–30% [116], it is a more common cause of chronic, intermittent, low-grade lower gastrointestinal bleeding in patients over 65 years old [117,118].

Pathophysiology

One explanation of the pathophysiology of diverticular bleeding is the hypothesis that as a diverticulum herniates, the vessel responsible for the weakness in the wall of the colon at that point becomes draped over the dome of the diverticulum, separated from the bowel lumen only by mucosa (see Fig. 61.1); with time, the artery is exposed to repeated local injury along its lumenal aspect secondary to inflammation or increased intralumenal pressure. Eccentric intimal thickening and thinning of the media occur in the vasa recta along the side adjacent to the lumen [27]. These localized changes in vessel wall structure may result in segmental weakness of the artery and rupture into the lumen. Right-sided diverticula tend to have wider ostia and domes than those in the left colon, possibly exposing vasa recta to injury over a greater length of the vessel wall and hence accounting for the higher incidence of hemorrhage recognized from right-sided colonic diverticula [27]. Others believe that the thinner wall of the right colon predisposes to diverticular bleeding [35].

Natural history

Bleeding will develop in 15% of patients with extensive diverticulosis; in a third of these patients (5%) the bleeding is massive and can potentially lead to cardiovascular instability [35]. Many patients are elderly (mean age, 68–77 years) [115,116] with comorbid conditions that contribute to morbidity and mortality rates of 10%–20% [116,119]. Several studies have suggested that management with a specialized bleeding team may decrease mortality [115]. Bleeding stops spontaneously during 75% of episodes; a requirement for blood transfusion of less than 4 units in 24 h is associated with spontaneous cessation of bleeding in 99% of patients [120]. The risk of rebleeding, however, is substantial, ranging from 14% to 38% [115,120]; with a second episode, the risk of further hemorrhage approaches 50% [120]. The right colon is the source of diverticular bleeding in 48%–90% of these patients [27,115,121] despite the fact that 75% of all diverticula are left-sided, and when right-sided diverticula occur, they are usually associated with left-sided diverticula [12].

Clinical presentation

The hallmark of diverticular bleeding is painless, bright red rectal bleeding. Most episodes are minor (< 1 unit of blood), and up to 50% of patients [121] give a history of intermittent passage of maroon or bright red blood. Abdominal pain is usually absent; indeed, it is extremely rare for bleeding to coexist with acute diverticulitis [27]. Physical examination is usually unremarkable without abdominal tenderness or mass. Less than 5% of patients with bleeding diverticulosis present with massive hemorrhage requiring transfusion; this bleeding is usually not of an acute exsanguinating form but rather as a persistent bleed.

Management

Management of massive colonic bleeding has three components: resuscitation, diagnosis and localization of the site of bleeding, and subsequent management. A coordinated approach by gastroenterologists, radiologists, and surgeons as members of a specialized bleeding team has been shown to decrease mortality [122]. The American College of Gastroenterology has published Practice Guidelines addressing lower gastrointestinal bleeding [123].

Resuscitation and initial assessment

After aggressive fluid resuscitation and cross-matching of blood, blood loss must be estimated, an assessment must be made of hemodynamic stability, and the source should be sought. The patient's age is not a great help in diagnosis nor is the physical examination. Rectal examination, anoscopy, and proctoscopy must be part of the initial assessment; massive hemorrhoidal bleeding, although rare, can be easily excluded. If there is a strong suspicion of bleeding from a lower gastrointestinal source, the appropriate diagnostic workup is initiated. If assessment does not indicate if bleeding is proximal or distal to the ligament of Treitz, an extended upper endoscopy should be performed because massive hemorrhage from the upper gut is statistically more likely than from the lower gastrointestinal tract (82% vs 18%)

[115,124]; if this investigation is negative, then evaluation of the lower gastrointestinal tract should begin.

Diagnostic modalities

The aim of the diagnostic evaluation is twofold: to localize the site of bleeding should operative treatment become necessary, and to determine the cause of bleeding, as treatment of diverticular bleeding differs from that of other causes. Radionuclide bleeding scan, mesenteric angiography, and colonoscopy have all been employed; the appropriate order in which they are utilized depends on the rate of bleeding and on available expertise. A combination of diagnostic modalities can identify successfully the source preoperatively in 90% of patients with massive bleeding [125].

Colonoscopy

The role of colonoscopy in acute diverticular bleeding is evolving but, in some centers, it has become the preferred initial approach. The first report of endoscopic management of a bleeding diverticulum with injection of 1 : 1000 epinephrine was in 1985 [126]. Success has since been reported with the heater probe [127], bicap probe [128], injection therapies [129,130], and fibrin sealant [131]. Endoscopic "stigmata" with prognostic value have been reported [132]. Cumulative results of small studies suggest a 95% rate of hemostasis [133]. Some proceed with emergent colonoscopy in unprepared bowel, as blood is cathartic [134]. Others use enemas or rapid preparation with balanced electrolyte solutions given orally or through a nasogastric tube [135,136]. When performed successfully (i.e., satisfactory visualization of the mucosal surface), colonoscopy has a diagnostic accuracy of 72%–86% [134–136]. Advantages include precise localization and the potential for therapeutic intervention. Only a select few patients, however, are realistically amenable to colonoscopy – those with low volume, intermittent colonic bleeding.

Radionuclide imaging

Two types of radionuclide bleeding scans have been employed. The first utilizes a sulfur colloid labeled with technetium (^{99m}Tc). Scans obtained shortly after intravenous injection can image the area of bleeding even if the rate of bleeding is as low as 0.1 mL/min. This method is exceedingly sensitive but the short half-life of the marker within the intravascular space (the sulfur colloid is rapidly cleared by the spleen and liver) limits the usefulness of this imaging modality to patients who are actively bleeding during the short duration that the label remains in the vascular space. Because of this exceedingly short functional half-life of efficacy, this imaging modality has been replaced with the so-called tagged red cell scan, which uses ^{99m}Tc pertechnate to label or tag autologous red blood cells removed from the patient before reinjection into the patient (Fig. 61.17). Abdominal images are obtained frequently during the first 30 min, and then every few hours for up to 24 h. The major advantage of this label is that patients may be scanned several times over 24 h and so it is possible to image the site of intermittent bleeding or localize the appropriate quadrant of the abdomen.

Radionuclide bleeding scans have advantages and disadvantages. Advantages are their noninvasiveness and sensitivity. One series demonstrated a sensitivity of 97%, specificity of 83%, and positive predictive value of 94% [137]. The disadvantages of radionuclide scans are that they localize

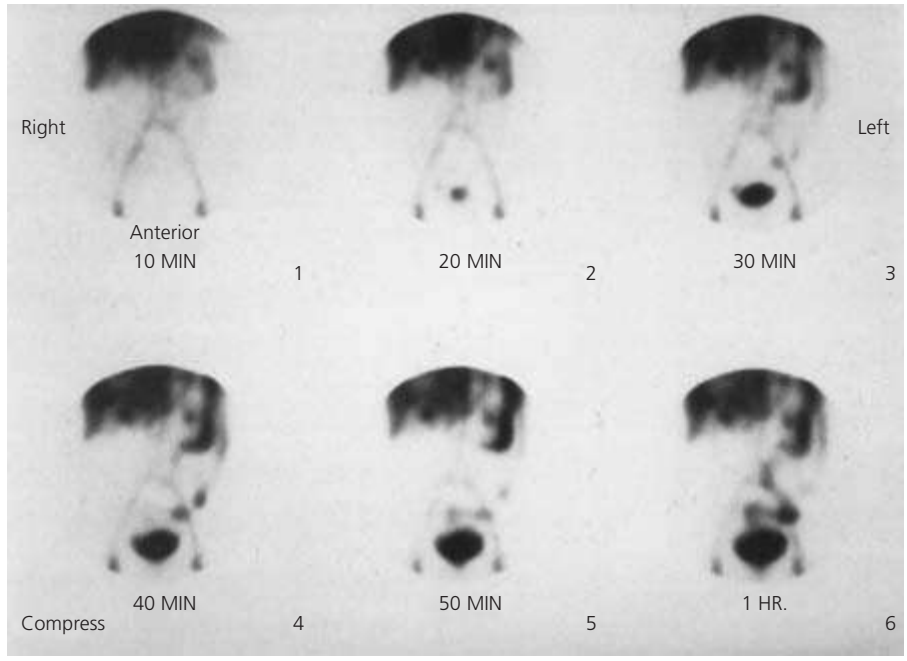

Figure 61.17 Technetium (^{99m}Tc) -labeled red blood cell scan for evaluation of lower gastrointestinal bleeding in a 63-year-old woman with a 24-h history of bright red blood per rectum. Increased activity in the distal transverse colon near the splenic flexure progresses towards the descending colon and sigmoid colon by termination of the examination at 1 h. Findings are consistent with a bleeding source in the distal transverse colon near the splenic flexure. From Young-Fadok & Pemberton [149].

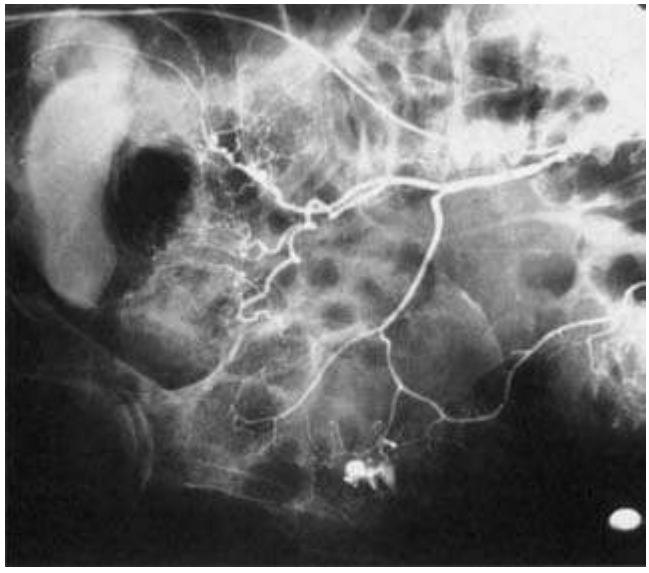
bleeding to a general area of the abdomen without necessarily localizing the bleeding source to a specific organ, for example, colon vs small bowel, and so accuracy rates range from 24% to 91% [35]. Poor organ localization occurs, because the extravasated blood may move within the hollow organ in either a peristaltic or antiperistaltic direction, and, in addition, localization to an area of the abdomen cannot objectively define a site in the colon; for example, bleeding from a redundant sigmoid colon may appear as extravasation in the right lower quadrant suggesting bleeding either from the right colon or the distal small bowel. Hence, radionuclide imaging is often used before angiography to confirm bleeding rates sufficient to justify the use of the more invasive selective angiographic studies.

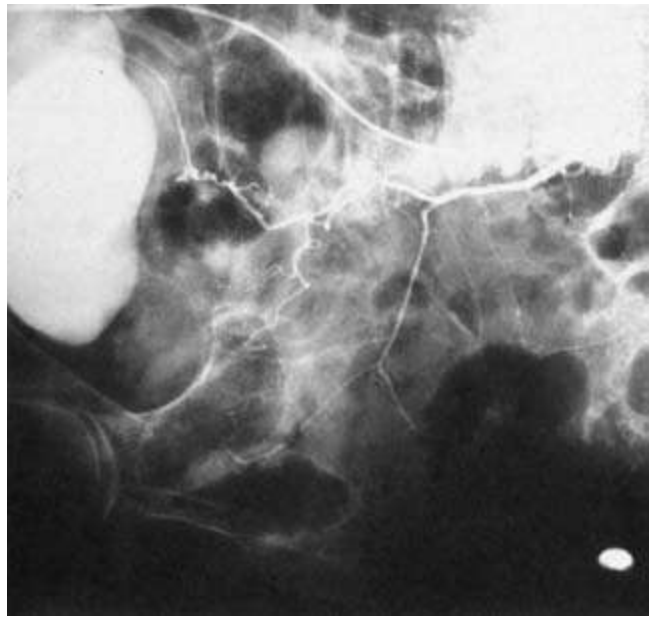
Angiography

In the absence of a likely source in the distal colon or rectum, the first mesenteric vessel examined is the superior mesenteric artery, as 50%–80% of diverticular bleeding and virtually all bleeding from angiodysplasia occur in segments of the colon and bowel supplied by this artery [138]. If no source is found, the inferior mesenteric and celiac vessels are studied. Successful localization of the anatomic site of bleeding varies from 14% to 72% [116,119,135,139] and depends on the rate of bleeding (sensitivities are as low as 0.5 mL/min), timing (the patient must be bleeding actively at the time of the intravenous contrast administration), and the expertise of the angiographer. Angiographic localization is 100% specific, but sensitivity varies with the pattern of bleeding; with acute bleeding, sensitivity approaches 50% but decreases to 30% with a pattern of recurrent hemorrhage [140]. A positive angiogram is associated with an 86% likelihood of operative treatment [140]. The use of radionuclide imaging to screen for active bleeding may decrease the frequency of negative arteriograms [124], but some groups maintain that the incidence of negative arteriograms is increased by the delay inherent in performing radionuclide scans [116]. Complications of urgent arteriography occur in about 9% of patients and include arterial thrombosis, mesenteric or peripheral embolization of atherosclerotic debris from the aorta, and renal failure [135].

The advantages of angiography are that bowel preparation is not required, and the anatomic localization provided is organ-accurate, especially in the colon. Moreover, angiographic techniques may allow therapeutic intervention with selective infusion of vasoconstrictor agents or vascular embolization. Vasopressin can be infused directly into the artery supplying the segment of colon bleeding by a subselectively positioned intraarterial catheter (Fig. 61.18). Up to 91% of patients receiving intraarterial vasopressin will stop bleeding; however, as many as 50% will rebleed on cessation of vasopressin [116]. In these patients, however, vasopressin may permit resuscitation, stabilization, and bowel preparation with the goal of resection and primary reanastomosis [116]. Transcatheter embolization is a more definitive means of controlling hemorrhage. Early studies were associated with an incidence of colonic infarction in up to 20% of patients embolized. Attempts to reduce this risk have included use of

(a)





(b)

temporary occluding agents or have employed a "superselective" catheterization technique [141]. Investigational studies in a canine model showed that when medium to large (420–1000 μm) polyvinyl alcohol particles were used, smaller vessels were preserved, maintaining intramural collateral microcirculation. Studies in both canine and porcine models have demonstrated no histological evidence of bowel infarction when microcoils are used to perform superselective embolization [142]. In humans, cumulative retrospective results have also confirmed that use of microcoil embolization minimizes ischemic complications [143].

Management approach

During resuscitation, the management rationale is determined by categorizing patients into one of three groups: hemodynamically unstable with active bleeding, continuing bleeding but hemodynamically stable, and hemodynamically stable with apparent cessation of bleeding (Fig. 61.19).

Hemodynamic instability

Persistent instability despite aggressive resuscitation requires emergency operative intervention in 18%–25% of patients with diverticular bleeding who require blood transfusion [120,144]. Every attempt should have been made to exclude an upper gastrointestinal source of bleeding (e.g., nasogastric intubation or even emergency gastroscopy), as the operative approach is markedly different for the surgeon. At operation, a careful exploration is undertaken looking for an obvious source or a mass. Because diverticular bleeding is not associated with acute diverticulitis, the involved diverticulum is not immediately evident externally. Indeed, most patients are elderly and would be expected to have colonic diverticula. Without preoperative localization, the decision of what or where to resect becomes problematic. Multiple techniques have been described, including dividing the colon into sections by applying occlusive clamps across the bowel and determining which section fills with blood; this technique,

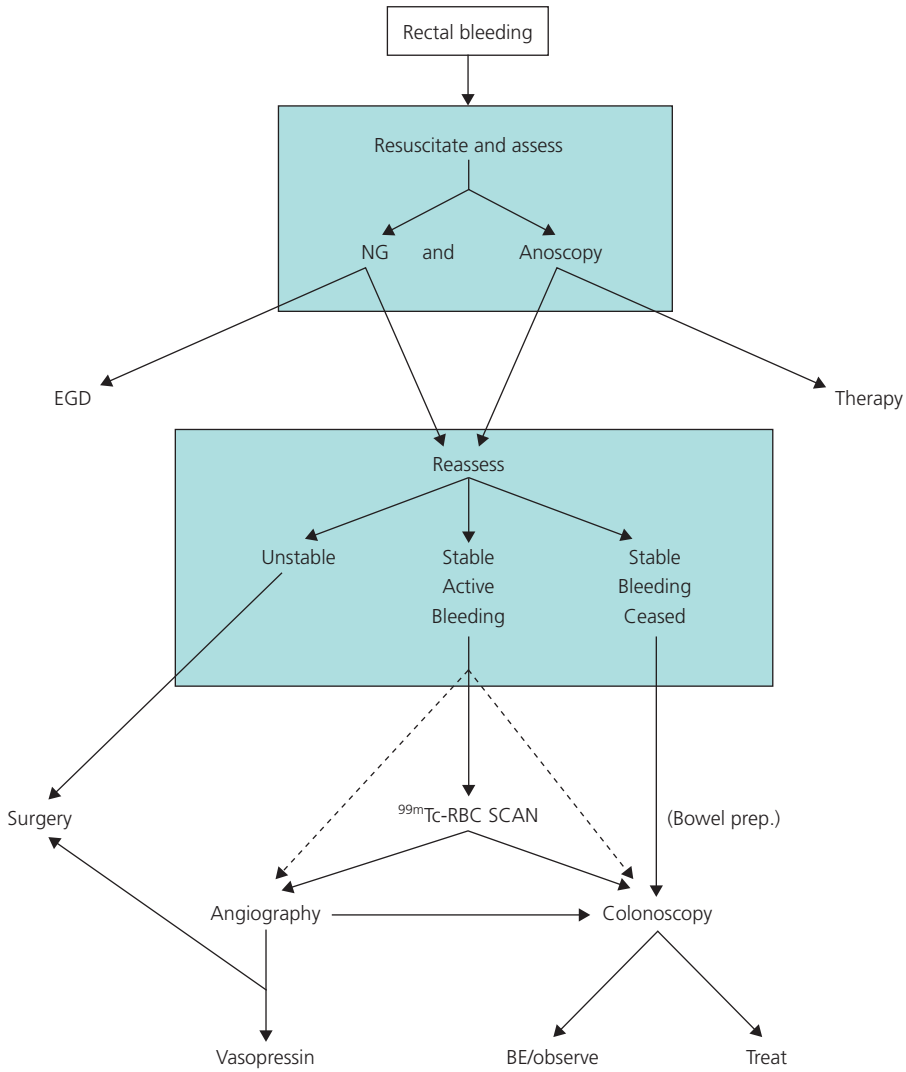

Figure 61.19 Algorithm for management of diverticular bleeding.

which requires the presence of ongoing massive bleeding, is generally unsatisfactory. A much better approach involves intraoperative colonoscopy [125], possibly after a rapid, on-the-table intraoperative bowel preparation using an infusion catheter placed into the cecum, through which a warmed electrolyte solution is infused rapidly and placement of a transanal catheter to control the efflux of infusate from below. This approach allows the possibility of a localized, segmental colectomy involving only the site of bleeding. If, however, no obvious colonic site can be identified, and the bleeding is massive and life threatening, the surgeon may need to perform an abdominal colectomy resecting the entire colon susceptible to diverticular and angiodysplasia. All possible attempts at specific localization preoperatively and intraoperatively are, therefore, important to limit the extent of the colectomy required. A source of bleeding is identified ultimately in 78% of patients undergoing emergent operation for lower gut bleeding [125].

Hemodynamically stable with continued active bleeding

The most straightforward approach is to start with a tagged red blood cell scan. If positive, it can serve as a useful screen before mesenteric arteriography, which may permit infusion of vasopressin to stop the bleeding and allow bowel preparation for future operative treatment should the bleeding recur. Infusion begins at 0.2 units/min, with repeat angiography after 20 min; if bleeding persists, the rate is increased to 0.4–0.6 units/min [145]. If the bleeding is controlled, then the infusion should be continued in an intensive care setting for 24–36 h and then tapered over 24 h [145]. In the high-risk patient who has failed the initial vasopressin trial but has substantial contraindications to operative intervention, embolization may be used followed by close observation for ischemic complications. If angiography is negative, the next step in the diagnostic algorithm (see Fig. 61.19) is colonoscopy, which may identify a source or localize the site of active bleeding. Diverticular bleeding is observed rarely at colonoscopy and is often a diagnosis of exclusion. If the radionuclide scan does not demonstrate bleeding, angiography is unlikely to be helpful. Colonoscopy is then performed after bowel preparation. Some institutions proceed directly to angiography, especially for massive bleeding, whereas others use a rapid bowel preparation before colonoscopy. Of note is that barium enema (vs water-soluble contrast) has no role in the management of acute colonic bleeding, as it prevents angiography because of retained barium.

Hemodynamically stable, bleeding stopped

The patient who has stopped bleeding provides a diagnostic challenge but also allows a semielective evaluation, which involves bowel preparation and colonoscopy in preference to contrast enema.

Operative treatment

The need for operative intervention varies with the degree of bleeding. With severe or massive rectal bleeding, 24%–78% will require operative intervention [116,120,125,135]. Preoperative localization of the site of bleeding and the use of vasopressin as a temporizing measure have decreased operative morbidity from 37% after emergency resection to 9% after segmental colectomy. The operative mortality of 9%–11% reflects comorbid conditions [116,125,144].

When the source of bleeding has been localized, a segmental colectomy is performed, and the rate of rebleeding is 0%–14% [116,120,146]. Blind segmental resection of the most involved diverticula-bearing segment carries a rebleeding rate as high as 42% [146] and an ultimate morbidity and mortality of 83% and 57%, respectively; it is, therefore, contraindicated [146]. Even in patients with extensive diverticular disease, if the site of bleeding has been localized objectively, a segmental resection eradicating the bleeding site is adequate [116]. Abdominal colectomy is reserved for the patient who continues to bleed without a documented site of bleeding but who has typically been associated with a relatively high morbidity and mortality (37% and 11%–33%, respectively) [116,120,147]. More recent studies, however, would suggest that subtotal colectomy can be performed with no excess morbidity or mortality compared with segmental resection [148]. Although the rebleeding rate after abdominal colectomy approaches 0% [146], abdominal colectomy can be associated with relatively disabling diarrhea in the elderly in about 15% and socially unsatisfactory diarrhea in a larger percentage. Therefore, this extent of operation should not be undertaken lightly.

Recent developments in screening tests, 1606
Other considerations in screening practice, 1607
Conclusions, 1608

Screening for colorectal cancer can be defined as the testing of asymptomatic people to classify them as likely or unlikely to have the disease [1]. The World Health Organization (WHO) has described the requirements that should be met before it is appropriate to screen [2]. Colorectal cancer meets all these criteria:

- it is a major health problem in many countries
- it has a latent stage
- there are appropriate proven screening tests
- testing is feasible
- treatment can lead to cure.

WHO recommends screening using a simple test. The result of the screening test determines who undergoes a diagnostic test.

Goals of screening

The goal of screening for colorectal cancer is to reduce mortality from or morbidity due to the disease. The natural history and the impact of early detection methods on outcome can be conceptualized as shown in Fig. 62.1. Presymptomatic detection of localized cancer (point S3) reduces morbidity or mortality. If screening detects preinvasive lesions, namely dysplasia or adenoma (points S1 or S2), it will reduce cancer incidence.

Ideally, screening is an ongoing process, which is directed at asymptomatic individuals who are at average risk for developing colorectal cancer [2]. Average risk is defined as age at least 50 years, absence of high-risk factors such as family or personal history of colorectal neoplasia, resident in a developed or developing country where the lifestyle is changing to that of Western countries, and absence of symptoms suggestive of colorectal cancer [3]. Screening should perhaps be avoided in those individuals where screening is not a health priority, such as when active major illness is present [4]. When high-risk factors are present, an individualized surveillance program is indicated based on specific circumstances.

The most immediate impacts of screening will be adenoma detection, down-staging of the detected cancers and prolonged survival after treatment. The longer-term impacts will be reduction in overall population mortality and incidence.

The contexts of screening

Screening for colorectal cancer is usually undertaken in either personalized or population settings [5]. The health imperatives driving each are different.

In some countries the traditional approach has consisted of a face-to-face meeting between the individual and a physician – sometimes referred to as *case-finding* or *individualistic* screening. It may be initiated by the individual or the physician. Here, the person can be assessed for symptoms and level of risk. What is offered is individualized and done in the context of counseling. Duty of care and doing what is best for the person drive the decision-making – cost-effectiveness tends not to be a consideration, although affordability and access are.

Population or *mass screening* involves an organized and systematic approach aimed at maximum participation in screening within a population. It seeks, through a standardized and often impersonal approach, to engage individuals in at least some form of preventive activity – in effect, doing something is better than doing nothing. Outcomes at the population level such as acceptability, feasibility, and low initial cost with proven cost-effectiveness are key issues. Many thousands will be tested in a short time frame, often without ascertainment of presence of symptoms or without profiling risk through a counseling process.

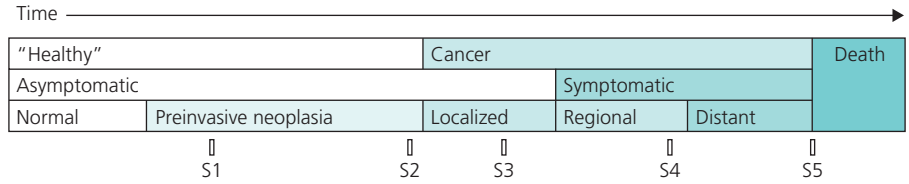

Figure 62.1 Schematic showing stages of colorectal oncogenesis as they relate to different points of early detection as might occur during screening (S1, S2, S3). Relative durations are meant to serve only as a guide. The impact of detection at each point is as follows: S1, detects many adenomas, a proportion of which might not be precursors of cancer but removal should lead to reduced incidence of and mortality from cancer; S2, detects fewer inconsequential adenomas but will remove adenomas and prevent cancer, thereby reducing incidence and mortality; S3, down-stages detected cancers and so will lengthen survival and reduce mortality through increased rate of cure; S4, lesser impact than at S2 but likely to reduce mortality to a degree; S5, probably no impact.

The nature of screening

No matter what the context, screening is by its nature a process that aims to improve the likelihood that affected people, while at a curable and usually unsuspecting stage, receive effective diagnosis and treatment. Screening is, therefore, a process with multiple phases as depicted in Fig. 62.2 [6]. Screening is only beneficial to the individual if the screening test is performed, if diagnosis is accurate, and if treatment is effective.

There are two main choices at the phase where a test is offered (Fig. 62.2).

- *One-step testing* The diagnostic test, colonoscopy, is offered. Selection for colonoscopy is based solely on age and many people will be found to have no neoplasia.
- *Two-step testing* A simpler test is offered first, e.g., a fecal occult blood test (FOBT) or flexible sigmoidoscopy, then those with a positive result proceed to colonoscopy. A simple screening test calls attention to the likelihood of disease being present and serves to direct resources to those most likely to benefit from diagnostic and therapeutic procedures [6].

Operational phases of the screening process proceed as follows:

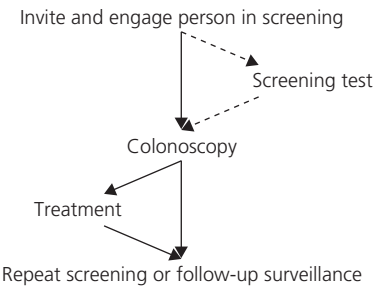

Figure 62.2 Diagrammatic representation of the screening process to demonstrate the main phases involved in the screening process and the options of one-step and two-step screening.

- *Invite and encourage* participation in a screening program.
  - Use either a personalized approach within a health-care environment, or
  - Use a mass population approach with wide coverage of the population.
- Where a person is found to have a *high-risk* factor (e.g., colorectal symptoms, family history or personal history of relevant colorectal disease), provide access to an individualized prevention strategy appropriate to that risk.
- Where a person is found to have *symptoms*, offer the appropriate diagnostic test.
- For those who are confirmed *average risk*, provide a safe, effective, acceptable, and affordable screening test in either of two main ways:
  - *two-step testing*: perform a simple test such as a fecal occult blood test (FOBT) to establish risk and select who should proceed to colonoscopy, or
  - *one-step testing*: perform colonoscopy.
- Facilitate *compliance* with any necessary diagnostic and therapeutic follow-up.
- Offer *rescreening* at the appropriate interval, having identified risk status.
- *Monitor* adequacy of participation, quality of tests and clinical procedures, availability of necessary resources, and the outcomes of the program.

The nature of screening tests

The nature of the major screening tests, either established or under study, and their place in the testing phase of the screening process, are summarized in Table 62.1. In general, the efficacy of screening for colorectal cancer is supported by the highest level of evidence, namely randomized controlled trials, at the population level. However, as summarized in Table 62.1, this is not the case for all of the test options. As the evidence is strongest for tests that detect fecal blood or for those that endoscopically visualize lesions, we will critically evaluate these approaches in detail.

Table 62.1 Overview of available screening tests describing basis for detection of neoplasia, strength of evidence for efficacy, and factors that limit sensitivity and specificity

Detection goal	Technology	Strongest evidence for benefit	Place in screening process	Sensitivity determinants	Specificity determinants
Fecal blood	Guaiac-based FOBT	Population RCT – reduced incidence and mortality	Two-step	Amount of fecal heme	Dietary heme; bleeding nonneoplastic lesions
	Fecal immunochemical test (FIT)	Comparative cohort – better sensitivity or specificity	Two-step	Amount of fecal globin	Bleeding nonneoplastic lesions
Fecal neoplasm-derived DNA	Multitarget fecal DNA test	Comparative cohort – assessing sensitivity and specificity	Two-step	Spectrum of mutations in lesion	Unclear
Visualize lesion	Colonoscopy	Case–control and cohort – reduced incidence and mortality	One-step	Quality of procedure	Histopathology
	Flexible sigmoidoscopy	Case–control – reduced mortality	One- or two-step	Quality of procedure; limited depth of insertion	Histopathology
Imaging of lesion	Barium enema	None	Two-step	Quality of procedure	Lumenal artifact; nonneoplastic pathology
	CT colonography	Comparative cohort – assessing sensitivity and specificity	Two-step	Quality of procedure; precision of technology	Lumenal artifact; nonneoplastic pathology

CT, computed tomography; FOBT, fecal occult blood test, RCT, randomized controlled trial.

Evidence of effectiveness

As screening is a process where the goal is reduction in population mortality, randomized studies at the population level where mortality has been shown to be reduced even when analyzed on an intention-to-screen basis, i.e., regardless of whether people offered the test actually took it, is the most reliable indicator of effectiveness. We present the evidence available for the best-studied screening tests – namely FOBT, flexible sigmoidoscopy and colonoscopy – with the intention of developing an evidence-based guide for how to undertake screening.

Fecal occult blood tests

The fact that microscopic bleeding may arise from curable cancers and adenomas, provides the basis for screening using an FOBT [7,8]. However, the biology of bleeding is complex and for FOBT screening to be effective, these tests must be used properly in a way that maximizes their ability to detect bleeding from neoplasia.

Types of fecal occult blood test: guaiac and immunochemical tests

Available FOBTs are based on two principal technologies: chemical and immunochemical. The major biological and technological features of these tests are outlined in Table 62.2 [5,6,8,9].

Chemical fecal occult blood test

The chemical tests (e.g., Hemoccult II) detect the peroxidase activity of heme. The majority use guaiac as the reagent. These guaiac-based FOBT (GFOBT) react to any peroxidase in feces (e.g., plant peroxidases or heme in red meat) and are affected by certain chemicals (e.g., vitamin C). Because heme is relatively stable in the gut (although slow degradation occurs in the colon), GFOBT may detect bleeding from any site in the gastrointestinal tract, including the stomach [11]. Development and interpretation of GFOBT results seem simple but in practice the test is not reliable without training [12]. Most tests employ a wooden spatula for sampling stools, which should ideally be kept clear of the toilet bowl water to avoid leaching of hemoglobin from the stool [13].

Other GFOBT more sensitive than Hemoccult, such as HemoccultSensa, have been developed although at the cost of worsened specificity, especially if red meat has not been excluded from the diet before a sample is collected [9,10]. HemoccultSensa is also more readable [14]. Some studies indicate that if development of GFOBT is delayed 72 h after sampling, the problem of plant peroxidase interference is minimized [14] and dietary restrictions for controlling GFOBT specificity can be simplified such that only red meat and very high-peroxidase foods such as horseradish need be excluded. Unfortunately, unpredictably high positivity rates still occur in several ethnic communities [10,15], resulting in GFOBT not being of practical use.

Table 62.2 Nature, usage, and performance issues for different types of fecal occult blood tests (FOBT) [5, 6]

Type of FOBT	Chemical basis	Diet restrictions	Drug interference	Site of occult bleeding detected	Specificity for neoplasia[d]	Sensitivity for cancer[d]
Chemical (GFOBT)	Guaiac detects peroxidase activity of heme	Required: Red meats Possibly certain raw plant foods[a]	Vitamin C Possibly NSAIDs[b]	Rectum > colon > stomach (in decreasing order of sensitivity)	90%–98% depending on test brand, and usage	35%–67% with one-time testing Over 80% with repeated testing
Immuno-chemical (FIT)	Anti-human hemoglobin antibody detects globin	None required	None	Colon and rectum	Around 95% depending on sensitivity level chosen[c]	65%–90% with one-time testing Unclear for repeated testing

a Delaying development for 72 h minimizes interference from plant foods and avoids the need for their restriction with standard Hemoccult II. Red meats must be restricted when using a more sensitive GFOBT [9].
b Low-dose aspirin is not a problem, but therapeutic doses, such as those used for rheumatic disorders, may be a problem.
c Tests generally provide a qualitative result, but some newer FIT can be quantifiable.
d Indicative estimates only derived from Tables 62.3 and 62.4 and reference [10].
FIT, fecal immunochemical tests for hemoglobin; GFOBT, guaiac-based FOBT; NSAIDs, nonsteroidal antiinflammatory drugs.

Before the availability of more sensitive GFOBT, rehydration of Hemoccult test cards was applied to increase sensitivity [16], but this has an adverse effect on specificity by activation of plant peroxidases [14]. Guidelines to standardize development have never been established and rehydration is no longer recommended [9,14,17].

To summarize, while of proven efficacy in decreasing colorectal cancer mortality and incidence, chemical FOBT, i.e., GFOBT, has the following shortcomings [8].

- Restrictions of diet and drugs are needed to optimize specificity, especially for the sensitive GFOBT.
- GFOBTs generally use spatula sampling of stools, and stools need to be kept out of contact with toilet bowl water.
- GFOBTs are not selective for colorectal bleeding.
- The end point can be difficult to read and is transient.
- Sensitivity for cancer is suboptimal for less sensitive GFOBT brands.
- More sensitive GFOBTs are subject to unpredictably high false-positive rates.
- GFOBTs are not suitable for automated mass development or reading of the result.

Fecal immunochemical tests

Fecal immunochemical tests for hemoglobin (FIT) use antibodies that are specific for human globin and, therefore, these tests are not affected by diet [11,18,19]. They are subject to less variability in positivity rate than the sensitive GFOBT [15]. Because globin is rapidly degraded by digestive enzymes, these tests are highly selective for occult bleeding of colorectal origin [11].

Depending on the version of FIT and the manufacturer, improvements in fecal sampling have been made; these are discussed elsewhere in detail [8,9,18,20]. The tests may be developed in the office or laboratory and quality assurance of test development is much improved. It is beyond the scope of this chapter to further describe the technological details but laboratory development is preferred in many countries, especially for mass screening when many tests must be performed and quality assurance is vital [5]. Most branded versions of FIT require fewer than three fecal samples, the recommended number for GFOBT.

Several of the latest FIT allow quantification of fecal hemoglobin. The advantage of fecal hemoglobin measurement is that it returns full control of sensitivity and specificity to the end-user [6,8] who can establish the level of fecal hemoglobin that would trigger colonoscopy. At the population level, such an approach allows the test specificity–sensitivity ratio to be maximized, so adapting the colonoscopy rate to the facilities and funds available for screening.

Table 62.2 provides estimates of sensitivity of the different types of the FOBT, i.e., GFOBT and FIT. As a general rule, FITs are at the more sensitive end of the range while GFOBT tests vary widely across the range. A detailed comparison of the different FOBTs has been reported [9] and a recent study has shown a brush-sampling FIT to be more sensitive for cancers and advanced adenomas than even the more sensitive GFOBT [18]. A large-scale study of over 7000 people undergoing screening in California is informative in this respect [10]. It shows that an FIT achieves the same sensitivity as a sensitive GFOBT but with better specificity, i.e., fewer colonoscopies. FITs overcome most of the disadvantages presented by GFOBT and it has been concluded that FIT should replace GFOBT [9,18,20].

Table 62.3 Nature of randomized controlled trials of two-step screening for colorectal cancer by guaiac-based fecal occult blood test

GFOBT, guaiac-based fecal occult blood test.

Screening by fecal occult blood test: evidence of effectiveness

Six controlled trials of screening based on GFOBT have been reported [16,21–32]. The five of these where there was no planned intervention in the control arm [16,21–31] are summarized in Tables 62.3 and 62.4. Follow-up ranged from 8.3 to 18 years for these trials. In all of these trials invitees were asked to sample three separate stools for testing by the GFOBT, as it has been shown that when a cancer is present bleeding may be intermittent [33].

Intermediate outcomes

All studies reported a favorable shift in stage of diagnosed cancers, with more stage A cancers or fewer stage D cancers detected in the screened compared with control groups (Table 62.4).

Test positivity rates, and hence colonoscopy rates, varied greatly between the studies mainly because of the type of test used, but also because of the frequency of testing and the length of the trial (Table 62.3). In the studies where the GFOBT Hemoccult was used without rehydration, positivity rates were low and colonoscopy intervention rates fell in the range 2%–4% [21–23,28–31]. Where the fecal sample was rehydrated before development, the proportion of people undergoing colonoscopy at least once during the trial period was as high as 38% (Table 62.3) [16].

Complication rates for follow-up of positive screening tests are available for several of the trials (Table 62.4). In the Minnesota trial there were 12 serious complications (perforations or major bleeds) per 10 000 offered screening [16]. No complications were reported in the Burgundy trial [31]. Higher rates were observed in Gothenburg [24]. Bowles and colleagues [34] reported a perforation rate alone of 12 in 9223 colonoscopies examined as part of a prospective audit and six deaths were considered as possibly being a result of the procedure.

Behavioral outcomes

In the four true population studies (Funen, Gothenburg, Nottingham, and Burgundy), participation in the first round varied between 53% and 67% (Table 62.4). Participation fell off in the subsequent rounds where only initial participants were reoffered screening but it was maintained when nonparticipants were reoffered screening (e.g., Burgundy) [31]. When the study groups consisted of volunteers, as in the Minnesota study, initial participation was higher.

Impact on mortality from colorectal cancer

All of the trials offered FOBT on a *repeated* basis. The Gothenburg trial offered screening only twice, i.e., two rounds, and did not see a significant impact on mortality (Table 62.4). All other trials offered more than two rounds of screening and all showed a significant impact on colorectal cancer-related mortality based on an intention-to-screen basis. Analysis on the basis of intention-to-screen takes into account acceptance of screening, not just test performance, and is the public health outcome of greatest impact.

Table 62.4 Outcomes in randomized controlled trials of two-step screening for colorectal cancer by guaiac-based fecal occult blood test

Site	Funen [21–23]	Gothenburg [24,25]	Minnesota [16,26,27]	Nottingham [28–30]	Burgundy [31]

Incidence of cancer, OR (CI)			Annual – 0.80 (0.70–0.90) (18 years) Biennial – 0.83 (0.78–0.94) (18 years)		1.01 (0.91–1.12) (11 years)
Major complications – colonoscopy		3/2296	15/12 246	"No deaths"	"None"

a Screen-detected lesions not whole screening cohort.
b Whole screening cohort.
CI, confidence interval; OR, odds ratio.

From Table 62.4 it can be seen that biennial screening with Hemoccult (not rehydrated) led to reductions in mortality of 14%–18% (Funen, Nottingham, and Burgundy trials [21,28,31]). A meta-analysis of the early results indicated a reduction in colorectal cancer mortality of 16% [25].

This effect on mortality seems modest but randomized controlled trials tend to underestimate the actual benefit of screening because of nonparticipation in the screened group and uncontrolled access to screening in the control group [35]. A better guide for magnitude of effect comes from the Funen, Nottingham, and Burgundy trials of actual participation in biennial screening with Hemoccult; mortality was reduced by 33%–41% in participants.

The Minnesota trial screened annually and used rehydration of Hemoccult to improve sensitivity [16]; it observed the greatest reduction in mortality on an intention-to-screen basis of 33%. The relative contribution of each is unclear because biennial screening in the Minnesota trial using rehydrated Hemoccult achieved a 21% reduction in mortality compared to the 14%–18% achieved with biennial Hemoccult in Europe. However, the Minnesota trial is the most informative for the magnitude of benefit because it had the best participation rate and the longest follow-up.

Impact on incidence (Table 62.4)

Cumulative incidence rates for colorectal cancer did not differ between the controls or screened groups in any of the trials by 13 years of follow-up. However, the Minnesota study by 18 years of follow-up (the longest) showed a significant impact on incidence whether screening was annual or biennial [27]. It seems likely that the higher sensitivity of rehydrated Hemoccult and the higher colonoscopy rate have resulted in a better detection (and thus removal) of adenomas.

Doctor's office or home-based fecal sampling?

Performing an in-office GFOBT as part of a digital rectal examination has been common practice [36]. However, usually only one stool sample, rather than the recommended

three, is obtained. The patient has not usually undertaken dietary preparation, which increases the risk of falsepositives with GFOBT [14], and there is always the concern that digital rectal examination will generate minor trauma [37]. FOBT as part of a digital rectal examination was only recently evaluated, in 2005, in a large group of asymptomatic subjects [38]. It was found that sensitivity for neoplasia was much better if 3-day sampling was performed compared to a single in-office test and a negative test did not reduce the odds of cancer being present. Screening based on digital sampling of stool as part of a rectal examination is not recommended.

Endoscopic screening tests: evidence of effectiveness

While the largest population screening trials have been undertaken using FOBT, the use of flexible sigmoidoscopy and colonoscopy for screening is also supported by evidence of impact on mortality of colorectal cancer.

Screening by flexible sigmoidoscopy

The evidence for efficacy of screening sigmoidoscopy comes from case–control studies, the design and outcomes of which are summarized in Table 62.5. In a case–control study of 66 subjects dying from colorectal cancer, the risk of dying was reduced by a single-screening flexible sigmoidoscopy (odds ratio [OR] 0.21; confidence interval [CI] 0.08–0.52) [39]. A similar study involving 261 cases of distal colorectal cancer found an adjusted OR, i.e., risk of death, of 0.41 (CI 0.25–0.69) in those who had had a rigid sigmoidoscopy within 10 years [40]. In both studies, the reduction in risk was limited to rectal and distal colonic lesions, i.e., to lesions within reach. More recent studies of flexible sigmoidoscopy (Table 62.5) continue to support the association [41,42] with similar risk reductions and benefit lasting 10 years or more after the procedure. Mandel [35] provides a critique of such case–control studies, pointing out that all such studies are liable to biases that overestimate the effect relative to randomized trials.

Screening sigmoidoscopy is challenged on the grounds that it represents an incomplete examination of the colon, albeit in the region where cancers are more likely [43] and if one is going to the trouble of performing an endoscopic examination, why not perform colonoscopy. Others see it as

Table 62.5 Outcomes in case–control and cohort studies addressing impact of endoscopic screening on colorectal cancer

Country	Design	Population	Intervention	Result	Duration of benefit	Reference
USA	Case–control	Dead from CRC, $n = 66$	Single flexible sigmoidoscopy	Dying from distal CRC, OR 0.21 (CI 0.08–0.52)	10 years	[39]
USA	Case–control	Dead from distal CRC, $n = 261$	Rigid sigmoidoscopy	Dying from distal CRC, OR 0.41 (CI 0.25–0.69)	10 years	[40]
USA	Case–control	"Incident CRC"	"Sigmoidoscopy"	Sigmoidoscopy done, OR 0.56 (men, CI 0.44–0.77). Similar in women, minimal impact on proximal CRC		[41]
USA	Case–control	Cases of distal CRC, $n = 1026$	Screening sigmoidoscopy	Sigmoidoscopy done, OR 0.24 (CI 0.17–0.33)	16 years	[42]
Germany	Case–control	Cases of CRC, $n = 320$	Sigmoidoscopy or colonoscopy	Endoscopy done, OR 0.28 (CI 0.16–0.48)	> 10 years	[50]
Israel	Case–control	Cases of CRC, $n = 40$ high-risk surveillance	Colonoscopy	Colonoscopy done, 48.7% of controls compared with 2.5% cases ($P < 0.05$)		[51]
Norway	Cohort	Screened vs not screened, $n = 400$ and $n = 399$, randomized	Flexible sigmoidoscopy initially, subsequent colonoscopy if neoplasia found	Developing CRC, RR 0.20 (CI 0.03–0.95)		[52]
Finland	Cohort	HNPCC complying vs refusing surveillance, $n = 133$ and $n = 119$	Colonoscopy at 3-yearly intervals	Developing CRC, 6% of surveillance vs 16% refusers ($P = 0.014$)		[53]

CI, confidence interval; CRC, colorectal cancer; HNPCC, hereditary nonpolyposis colorectal cancer; OR, odds ratio; RR, relative risk.

an efficient way to access a majority of colonic neoplasia at low cost, and include polypectomy as part of the procedure [44]. There are concerns about feasibility in terms of adequate numbers of proceduralists and inadequacy of reimbursement [45].

Until the randomized population studies under way in the UK, Italy, and the USA (the PLCO study) [46] are complete and adequate cost-effectiveness studies are undertaken, it is not possible to reach a firm conclusion on the place for flexible sigmoidoscopy in screening.

Screening by colonoscopy

Colonoscopy has long been established as a powerful diagnostic tool for colorectal neoplasia. It is also therapeutic in that successful removal of many adenomas and even early malignant polyps can be undertaken during the procedure. Cohort studies have demonstrated that polypectomy in people prone to develop polyps reduces the risk of cancer [47]. The technology is well established and the reader is referred to other relevant chapters for further discussion on its implementation and practice. Colonoscopy as a screening test is often justified on the basis that it is the most accurate test. Accuracy, however, should not be the sole criterion for choosing a screening test [6,48,49].

The evidence for efficacy of screening colonoscopy for reducing risk of or mortality from colorectal cancer comes from a few case–control studies and small randomized studies [50–53], summarized in Table 62.5. The magnitude of benefit seems large but the studies are small and there are several biases that magnify the effect [35]. The largest, a case–control study of 320 cases, found an OR of 0.28 (0.16–0.48) for diagnosis of colorectal cancer where screening sigmoidoscopy or colonoscopy had been undertaken [50].

Further evidence to support the use of screening colonoscopy comes from the FOBT trials because without colonoscopic follow-up of a positive test, these trials would not have shown benefit. Some argue that further proof of efficacy, in the form of randomized controlled trials, is unnecessary [54] because colonoscopy is more accurate.

Colonoscopic screening has been calculated to be a cost-effective strategy. Several studies have examined effectiveness and incremental cost-effectiveness of multiple screening strategies [48] and two found colonoscopy every 10 years to be the most effective [55,56]. In contrast, a model developed by Lieberman [57] showed that fecal occult blood testing alone was the most cost-effective strategy, but colonoscopy every 10 years became the most cost-effective strategy if the cost for diagnostic colonoscopy was under US$ 750.

How often should endoscopic screening be performed?

For flexible sigmoidoscopy, 5-yearly screening intervals are recommended based on the apparent protection for at least 5 years shown in the case–control studies. Screening flexible sigmoidoscopy may be performed in combination with GFOBT for better detection of proximal lesions although there is little evidence to indicate how much gain is achieved.

For screening colonoscopy, the question of how often to do it in people with average risk remains unanswered. There has been no large prospective study reported that addresses this. If screening colonoscopy is to be a once-only event, then the age at which it is performed is critical [58]. Once-only screening is only sound if we can be confident that most cases destined to develop colorectal cancer in their lifetime will have a "sentinel" lesion at the time the colonoscopy is performed.

When choosing an interval for screening by colonoscopy, there are clues from the few case–control studies where intervals of at least 5 years, and sometimes 10 years, seem justified [50–52]. Some consensus recommendations, e.g., that of the USPSTF [48], recommends 10 years in average risk people. However, cancers may be missed and interval cancers occur in surveillance programs in high-risk individuals [59,60] Without evidence from formal randomized trials, it is not possible to be confident about the appropriate interval.

Is colonoscopy the screening test of first choice?

There are several perspectives to this question and they arise from the two main contexts of screening discussed above.

In the context of individualized screening, differential sensitivity of colonoscopy against FOBT or flexible sigmoidoscopy becomes a consideration in practice, because people often want what is perceived as being best. Colonoscopy is clearly more sensitive [61–63].

On the other hand, some argue that there is a strong case for caution before colonoscopy is accepted as the ideal screening test [48], especially as part of a programmed public-health initiative. Many points must be considered.

- The sensitivity of colonoscopy compared to once-only sigmoidoscopy or FOBT overestimates the benefit. Repeated application of FOBT results in compounding of sensitivity, probably because the dwell time of a curable lesion is longer than the screening interval, meaning that curable lesions may still be detected in a subsequent round of testing. This is borne out in practice: sensitivity of once-only Hemoccult has been shown to be less than 40% [10] yet cumulative sensitivity of unhydrated Hemoccult in the Minnesota trial was 80% (Table 62.4).
- Is the lower sensitivity of the simpler screening tests for advanced neoplasms truly unacceptable? For flexible sigmoidoscopy, the deduced miss rate for advanced proximal neoplasms has been estimated at 24% [61] but the risk of advanced proximal neoplasms progressing to fatal cancer is relatively low, estimated at 1% per year [64–66].
- Colonoscopy is not perfect in practice and lesions are missed [59, 60, 67–69]. Flat lesions in particular are easy to miss during conventional endoscopy [44] and flat or depressed adenomas may progress more rapidly to cancer

than polypoid adenomas. If the cancers that are most likely to be fatal are those that develop and grow rapidly [48, 70], there is an advantage to a screening program that allows multiple chances to detect an existing lesion rather than testing just once every 10 years [48,70].

- The serious complication rate with colonoscopic screening is not trivial. One study, where all procedures were carried out by skilled operators, reported a rate of 33 per 10 000 people screened [34]. This is over twice the rate with FOBT screening (Table 62.3).

Colonoscopy may uncover the largest number of neoplasms and minimize the likelihood of missing any colorectal neoplasia but screening policy is not decided by effectiveness alone. If alternative screening strategies can significantly reduce the death rate from colorectal cancer but at an acceptable or lower cost and risk than those associated with colonoscopy, these strategies would be appropriate. The incremental effectiveness of colonoscopy needs to be large enough to justify its disadvantages (considerable manpower and financial resources, bowel preparation, conscious sedation, and serious potential complications). The millions (i.e., almost 95% of the general population) who will undergo colonoscopic screening for no apparent gain are subject to harms that could cumulatively outweigh the benefit to the much smaller number found to have significant colorectal neoplasia [49].

Summary of the effectiveness of available screening tests

Guaiac-based fecal occult blood tests and fecal immunochemical tests

It can be concluded from this evidence that screening of the general population, most of whom will lack high-risk factors, using a GFOBT is justified. The data show that screening should be repeated, with intervals of 1 year possibly giving a better effect than biennial screening. It should be noted that participants in the GFOBT trials were asked to sample three stools in the home environment. There is no evidence that collecting fewer samples by digital rectal examination in the physician's office is effective. Use of a sensitive GFOBT is preferred to rehydration of Hemoccult. Overall, FITs overcome most of the disadvantages presented by GFOBTs. Based on performance, FIT should replace GFOBT in screening for colorectal cancer [18].

Such recommendations are consistent with consensus recommendations from many national or professional groups [17,48]. Most bodies recommend that screening starts in the general population (i.e., undefined or average risk) at age 50 years, because around 90% of colorectal cancer occurs after that age. Cost-effectiveness of screening the general population at a younger age is of questionable value.

Colonoscopy and flexible sigmoidoscopy

On the basis of the studies described above it can be concluded that endoscopic screening will be effective. However, compared to GFOBT, we lack evidence from randomized controlled trials that address acceptability, incremental benefit and complication rates – it is important to understand the balance of risks and benefits. Because case–control studies tend to overestimate benefit, we cannot be certain of the magnitude of incremental benefit provided by endoscopic screening compared with FOBT screening.

Recent developments in screening tests

A recent American Gastroenterological Association Future Trends Committee report on emerging screening and diagnostic technologies for colorectal cancer [19] identified a range of tests and procedures that might be appropriate. These include proteomics or the analysis of broad protein patterns, making it possible to assess small amounts of protein for the presence of identified cancer markers using new protein assessment tools and computerized artificial intelligence analysis. In addition, high-magnification chromoscopic endoscopy [71], spectroscopy, and optical coherence tomography show promise as adjuncts to traditional colonoscopy. Fecal DNA testing also provides new options. The better studied advances, such as stool DNA testing and computed tomography (CT) colonography, will be discussed in some detail.

Fecal DNA tests

Cells shed from cancers and adenomas are detectable in the stools [72]. Detection of molecular or genetic events that either cause cancer or else reflect development of neoplasia could theoretically be useful in selecting who undergoes colonoscopy. Because of the molecular heterogeneity of DNA in neoplasms, selecting the best panel of markers represents a challenge.

The first large-scale evaluation of the value of fecal DNA testing (using a 21-mutation multitarget panel) as a possible first-step test in two-step screening for colorectal cancer has recently been reported [73]. The present version of the stool DNA test is costly (in excess of US$ 400) and requires a cumbersome stool collection that needs to be rapidly delivered to the processing laboratory [74]. The comparators were colonoscopy as the diagnostic reference standard and Hemoccult II (unhydrated) as the proven first-step screening test. A cohort of 4404 subjects completed all three tests and their results were analyzed in a subgroup of 2507, which included all subjects found to have neoplasia. The detection rate of cancer using the fecal DNA panel was 16 of 31 (52%) compared with 4 of 31 (13%, $P = 0.003$) for Hemoccult II. The reported sensitivity of Hemoccult II was substantially lower than that reported in other studies for one-time testing [10] and so it cannot be concluded that Hemoccult, a much cheaper test, is necessarily inferior. The performance of both tests for detecting advanced adenomas was similarly disappointing; 61 of 403 (15.1%) for fecal DNA compared with 43

of 403 (62.7%) for Hemoccult II. In those with negative colonoscopy, 5.6% had tested positive on fecal DNA compared with 4.8% on Hemoccult II (specificities of 94.4% and 95.2%, respectively). Fecal DNA testing did not identify the majority of neoplastic lesions found at colonoscopy and in this format it does not yet represent an advance over the much cheaper FOBT types [74].

It is expected that within the next decade, this innovative technology will eventually lead to more specific and simple tests that will provide an effective first test in a two-step screening process. The newer stool molecular tests might be based on RNA or protein markers that are subject to lesser heterogeneity than DNA tests. A more detailed review is presented by Young [20].

Computed tomography and magnetic resonance imaging colonography

Virtual colonoscopy, also known preferably as computed tomographic colonography (CTC) was first described in 1994. It is an imaging method for detecting pathology in the colon and rectum that is less invasive than colonoscopy [75].

It has been pointed out that CTC avoids some of the drawbacks of colonoscopy, such as the need for intravenous sedation, recovery time, and assistance with transport [76]. The risks of bleeding, perforation, and side effects of sedatives will be much less than with colonoscopy. As the majority of screening colonoscopies identify no clinically significant pathology, CTC, as with other first-step tests such as FOBT, should reduce unnecessary colonoscopies.

With the latest equipment, CTC takes 10–15 min. Advances in software now allow for typical reading times of 10 min or less and final reports can be issued within 2 h. It might eventually prove possible to avoid colonic cleansing using "preparation-less" CTC where an ingested contrast material is used to "tag" lumenal content. Imaging software digitally subtracts tagged material by a process known as electronic cleansing [77].

Performance characteristics of screening CTC have been difficult to assess because CTC is a technology undergoing rapid improvement. In a metaanalysis of 33 studies providing data on 6393 patients [78], sensitivity was 48% for polyps less than 6 mm, 70% for polyps 6–9 mm, and 85% for polyps larger than 9 mm. Specificity also varied according to size: 92% for detection of polyps less than 6 mm, 93% for polyps 6–9 mm and 97% for polyps larger than 9 mm. A weakness of the Mulhall analysis was that only a few studies included in the metaanalysis used the latest technology.

The use of the latest technology including electronic cleansing and multidetector CT scanners which permit faster higher resolution imaging than single detector scanners has been reported on by Pickhardt and colleagues [68]. They prospectively evaluated 1233 average-risk asymptomatic adults who underwent CTC and same-day conventional colonoscopy. The sensitivity of CTC for adenomatous polyps was 93.8% for polyps at least 10 mm in diameter, 93.9% for polyps at least 8 mm in diameter, and 88.7% for polyps at least 6 mm in diameter. The sensitivities of optical colonoscopy for adenomatous polyps were 87.5%, 91.5%, and 92.3% for the three sizes of polyps, respectively.

While such results are excellent, the practical application of screening CTC requires resolution of the following factors [76,79,80].

- Results in practice are not comparable to those of specialized centers.
- Can some polyps be safely left in place because chance of progression is very low. In other words, which types of lesions require immediate follow-up colonoscopy?
- CTC would ideally be coordinated with follow-up colonoscopy on the same day.
- The workload generated by false-positive CTC, caused by fecal matter, nonadenomatous polyps, or insignificant adenomas, remains unclear.
- Detection rate of flat adenomas by CTC is unclear [81].
- Population acceptance of a procedure that is uncomfortable and that requires time and possibly bowel preparation remains unclear. "Preparation-less" CTC is an unknown at present.
- The impact of finding extracolonic pathology is unclear. One study has undertaken a cost-effectiveness analysis [82]; 118 of 432 subjects (27.3%) had extracolonic lesions. In 7.4% it was felt that findings were clinically relevant and in 2.1% it was felt that subjects may derive a clinical benefit from treatment. Clinical follow-up added just 14.2% to the cost. Such findings suggest that extracolonic lesions might not pose a major problem.
- The cost-effectiveness of population screening with CTC is unclear.

Computed tomographic colonography has the potential to be a valid first-step screening test for colorectal cancer. It can accurately exclude the presence of large polyps and, by inference, cancer with high confidence. Technology improvement is likely to make it more sensitive for target lesions and perhaps more acceptable to those being screened, in the not too distant future. If shown to be cost-effective and applicable to large populations of average risk individuals, it may stand beside other established first-step screening tests such as FOBT, flexible sigmoidoscopy, and colonoscopy.

Other considerations in screening practice

As screening is a process, it is important that each step is feasible, otherwise benefit will not be obtained. Sustainability is also important because screening is unlikely to have a major impact if it is a one-time event in a person's lifetime [74].

Without participation there can be no detection [6]. Removal of dietary restrictions in several populations has been shown to enhance participation in screening with FOBT

[83], in one study by 28% [84]. The brush sampling method also simplifies the process and enhances it by 30%. Together, these two advances increase participation by 66% [84]. Obviously, FIT is superior to GFOBT in terms of both participation and performance and should replace GFOBT in two-step screening.

Capacity to undertake colonoscopy, whether as a follow-up assessment of those with a positive FOBT or as a one-step colonoscopic screening test, is critical. Many countries, perhaps all, are unable to comprehensively resource one-step colonoscopic screening. Evidence suggests that the manpower necessary to provide a skilled colonoscopic examination for all age-eligible people in the United States is insufficient [85,86].

Managing risk and duty of care

It is of paramount importance that risks as well as benefits are carefully explained to those being invited to take part. Informed consent must be obtained and the patient must be told that even with colonoscopy, it is possible that polyps or cancers may be missed. As two-step screening is effective and directs colonoscopy to those more likely to have neoplasia [6], there is a duty of care to offer this option. It is important to indicate that better sensitivity of colonoscopy is at the cost of more procedures and higher risk of complication to the screened person.

Conclusions

Screening for colorectal cancer detects unsuspected neoplasia and leads to its removal such that death or suffering from colorectal cancer is avoided. Proof of the value of screening is available even when studies are evaluated at a population level on an intention-to-screen basis where nonparticipating invitees are included in the analysis.

Two-step screening based on FOBT as the initial test is proven to be effective by population randomized controlled trials. FIT has emerged as the FOBT of choice because of a better sensitivity/specificity balance than GFOBT and better population acceptance. Collection of two or three samples for FOBT testing is necessary and there is no evidence that a single fecal sample collected by digital examination in the office is an effective screening strategy. Flexible sigmoidoscopy, while effective as judged from case–control studies, is initially invasive, inconvenient, and uncomfortable compared to FOBT. It will miss proximal lesions although misses can be reduced by coupling with FOBT. The results of the randomized trials of flexible sigmoidoscopic screening are needed before a clear conclusion can be reached on its role.

One-step screening by colonoscopy is likely to provide benefit but incremental cost–benefit and risk–benefit relative to FOBT screening is not clear. Colonoscopy is more likely to be accepted in the context of individual screening where there is face-to-face discussion with a physician. Acceptance at the population level where the offer of screening is more impersonal but also more consistent with the modern lifestyle, is unclear and not likely to be good. Estimates of the workforce required to deliver comprehensive colonoscopic screening raise doubt as to the practicality of using colonoscopy as a public-health initiative.

Fecal DNA tests and CTC are potential additions to FOBT in two-step screening but much more data on their effectiveness, acceptability, and cost–benefit are needed before they can be accepted for routine use. Stool molecular tests hold great promise for the future, especially if they can serve as sensitive and specific tests to identify those who have adenomas.

Screening should not be seen as merely the performance of a one-time test. Repeated testing improves benefit.

On balance, screening of average-risk subjects by the one-step or two-step approach is appropriate practice, starting at age 50 years. An FOBT, preferably of the FIT type, should be undertaken at least as frequently as 2-yearly (biennial), while the maximum safe interval for screening by flexible sigmoidoscopy and colonoscopy remains to be ascertained from prospective studies.

Impact of polypectomy on cancer, 1630

A *polyp* is any protrusion above the mucosal surface. Polyps may take various sizes and shapes, including sessile or pedunculated. They can also be described according to texture of the mucosal surface, position, color, ulceration, bleeding, and histological type. Polypoid lesions of the large bowel are normally classified into three main subgroups (Table 63.1): epithelial polyps, subclassified into neoplastic polyps (consisting of adenomas or carcinomas [1,2]) and nonneoplastic polyps; and submucosal lesions (which produce a polypoid appearance).

Colorectal polyps are important for several clinically relevant reasons. First, they are easily detected and removed with modern flexible endoscopes (see Chapter 126). Largely because of this, our understanding of their role as precursors of colorectal carcinoma has increased. Ready access to polyps has led to the elucidation of the genetic basis of the major inherited polyposis syndromes. Finally, intervention trials aimed at removal of adenomas or reduction of metachronous (newly developing) adenomas have demonstrated polypectomy to be valuable for controlling colorectal cancer [3–5] (see Chapters 65 and 126).

The natural history of the adenomatous polyp is variable, but it seems that when progression to carcinoma occurs it generally takes 3–7 years, although the progression of adenomas in patients with hereditary nonpolyposis colorectal cancer (HNPCC) appears to be faster.

Management of the patient with a colorectal polyp requires an understanding of the pathology, epidemiology, etiology, clinical manifestations, and course as well as the appropriate diagnostic studies and therapeutic options [1,2].

Epidemiology

Prevalence

Information on the prevalence of polyps comes from autopsy studies and from colonoscopic surveys, which are of a much smaller scale. Autopsy studies generally show a higher prevalence of polyps and adenomas than endoscopic studies. Prevalence rates vary considerably between gender (males more common), ethnic groups, and countries, and reflect the rates of colorectal cancer in those population groups (see Chapter 63). In the United States, autopsy studies suggest an overall polyp prevalence of up to 50% [6,7], but colonoscopic surveys suggest no more than 40% [8–15]. In autopsy studies, fixation of the colon and careful use of a magnifying glass allow detection of small polyps that are more readily missed during colonoscopy [16–20].

More than 90% of polyps detected at colonoscopy are epithelial in origin, that is, adenomas or hyperplastic polyps, and 75% of these are adenomas [8–13]. In the case of diminutive epithelial polyps (less than 5 mm), about half are hyperplastic [14,15].

Age is the major determinant of adenoma prevalence [6,7]. Size at detection also increases with age [20]. Colorectal adenomas are uncommon in patients younger than 30 years of age.

Anatomical distribution

Studies show that colorectal adenomas are more common in the distal colon and rectum, similar to the distribution of colorectal cancer (see Chapter 63). Distribution, however, relates to size. Small adenomas are more uniformly distributed throughout the entire colon, whereas large adenomas (greater than 1 cm) show a distal predominance [7,8,21,22].

Table 63.1 Classification of colorectal polyps according to tissue plane and pathology

Epithelial		
Neoplastic	**Nonneoplastic**	**Submucosal**
Premalignant (adenomas)	**Inflammatory**	Lymphoid collection
Tubular	Hyperplastic	Pneumatosis cystoides intestinalis
Tubulovillous		Colitis cystica profunda
Villous		Lipoma
Low-grade dysplasia		Carcinoid
High-grade dysplasia (intraepithelial carcinoma)		Metastatic lesions
Serrated		Hemangioma
		Fibroma
		Endometriosis
		Leiomyoma
Malignant (carcinomas)	**Hamartoma**	
Carcinomatous or malignant polyp	Juvenile	
	Peutz–Jeghers	

Association of adenomas with other diseases

Associations between colonic polyps and other diseases, apart from the polyposis syndromes discussed in Chapter 63, are infrequent. In a prospective study of acromegalic patients, nearly 50% had adenomas, increasing in prevalence with age [23].

Nonneoplastic polyps

The epidemiology of nonneoplastic polyps is not well studied except for the hyperplastic polyp, the second most common colorectal polyp [14,24]. Hyperplastic polyps usually are less than 5 mm in diameter and are most commonly found in the rectosigmoid area. Some studies have found an association between distal hyperplastic polyps and more proximal adenomas and colorectal cancer [25–30] but others have not [31–33], especially in the asymptomatic screening setting [33–37].

The predominant evidence from the larger and better controlled studies would suggest that hyperplastic polyps are not premalignant and do not signify a risk for colorectal neoplasia. In the US National Polyp Study, individuals with distal hyperplastic polyps were no more likely than those without to have more proximal colorectal neoplastic polyps [31]. Where associations are found, the relative risks are not clinically significant, and should therefore not determine clinical practice. Risk factors for hyperplastic polyps and adenomas are, however, surprisingly similar, complicating the interpretation of studies of associations with cancer to each type of polyp [38].

Hyperplastic polyposis and serrated adenomas

Individuals with *multiple* hyperplastic polyposis are clearly at increased risk of colorectal cancer [38]. Perhaps relating to this, molecular studies indicate that large right-sided sessile "serrated" hyperplastic polyps are prone to oncogenetic and epigenetic changes leading to genetic instability and neoplasia [39–41]. The descriptor "serrated" refers to the distinctive sawtooth architecture on histopathology. Serrated adenomas have the additional feature of neoplastic nuclei, that is, dysplasia (see Features of neoplastic polyps: Serrated adenomas and mixed hyperplastic–adenomatous polyps).

Clinically, sessile serrated polyps and serrated adenomas are associated with the syndrome of hyperplastic polyposis. This association might represent an extreme end of a clinical spectrum, driven perhaps by an as yet undiscovered germline predisposition. The syndrome and its inherent risk for malignant disease should be considered when hyperplastic polyps are numerous (more than 20, i.e., polyposis), are large (> 1 cm), are proximally located (especially if more than five are proximal to sigmoid colon), and especially when there are serrated adenomas. A family history of hyperplastic polyposis is uncommon (suggesting a recessive disorder) but colorectal cancer in a first-degree relative of a patient with hyperplastic polyposis is common and reflects inherited increased risk, perhaps associated with the putative heterozygous state [40].

Etiology and pathogenesis

The etiology of colonic polyps varies with histological type. For instance, inflammatory polyps result from the inflammatory and regenerative responses to injury whereas neoplastic polyps result from DNA aberrations. The remainder of this section focuses largely on neoplastic polyps because of their clinical significance and prevalence.

Adenomas are benign neoplasms; all show dysplasia (by definition). Dysplasia is characterized by cells with enlarged,

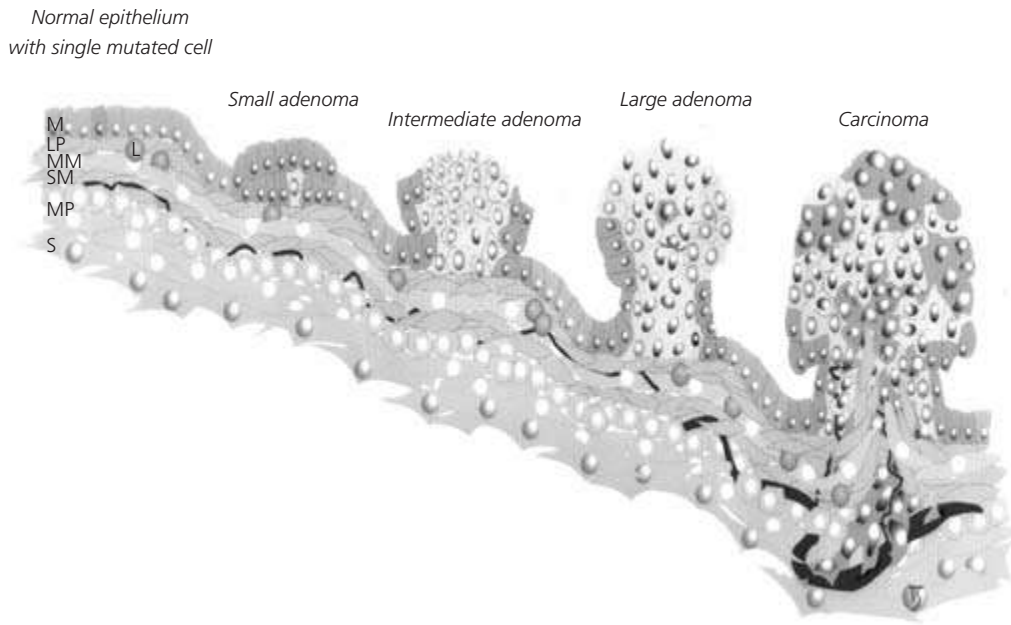

Figure 63.1 Model of development of a malignant colorectal carcinoma by a series of phenotypic changes and related genetic alterations. **Normal epithelium:** A single cell, frequently with a mutation in the *APC* gene (on chromosome 5), will give rise to the small adenoma in the next stage. **Small adenoma:** At this stage, when dysplasia is usually mild, both alleles of *APC* are affected by deletion or truncation (chromosome 5q). Changes in the level of methylation of DNA also may be observed. Note that a single cell in the clone has acquired an additional mutation in its *KRAS* gene (chromosome 12p). **Intermediate adenoma:** The cell with the *APC* and *KRAS* mutations has given rise to a new clone, forming an intermediate adenoma. An additional mutation in one of the cells, such as loss of heterozygosity (LOH), followed by deletion of a tumor suppressor gene (such as *DCC* [deleted in colorectal cancer] on chromosome 18q), gives this cell an additional survival advantage. **Large adenoma:** The cell with mutations and deletions in the *APC* and *KRAS* genes and LOH on chromosome 18q has clonally expanded into a large adenomatous polyp that has not invaded underlying mucosal layers. One cell of this clone acquires an additional mutation in the *p53* gene (chromosome 17p). **Carcinoma:** The cell that has accumulated mutations in the *APC KRAS* and *p53* genes and developed LOH on chromosome 18q has grown into a clone of malignant cells that penetrates through the lamina propria and invades underlying tissues. Note how cells are capable of lysing capillary walls and entering the vessels to be transported to distant sites where they form metastatic tumors. (Additional changes to proteolytic enzymes such as urokinase or telomerase may be required for metastatic behavior.) M, mucosa; LP, lamina propria; MM, muscularis mucosae; SM, submucosa; MP, muscularis propria.

hyperchromatic, elongated, and less polar nuclei often arranged in a picket-fence pattern (i.e., somewhat stratified), with variably decreased cytoplasmic volume, stroma, apoptosis, and cellular mucin, and variably increased numbers of mitotic cells. These changes result in a more basophilic appearance to the adenomatous epithelium in hematoxylin–eosin-stained sections [42,43]. Dysplasia ranges from mild to severe (Fig. 63.1). The terms *severe dysplasia* or *high-grade dysplasia* have been used synonymously with, and are preferred over, the terms *carcinoma in situ* or *intraepithelial cancer* when the severely dysplastic cells are confined within the basement membrane [44,45]. High-grade dysplasia is characterized by marked cytological change with disordered crypt architecture. Adenomas may be classified by predominant histology; tubular adenomas are the most common, constituting 80%–85% of all adenomas [46,47]. Tubulovillous adenomas constitute about 10%, with villous adenomas making up the remaining 5% [47].

Increasingly, studies refer to "advanced" adenomas. Definitions vary, but usually this refers to adenomas that are either 1 cm or larger in any dimension, or have a villous component (> 25% villous) or have high-grade dysplasia. Some reports also include the setting where a patient has multiple (three or more) adenomas even if the above features are not present [48]. This concept has evolved to identify patients at greater risk of developing cancer, with the implication that prevention or detection of advanced adenomas is a more useful target than detection of small tubular adenomas without severe dysplasia. There is empirical evidence to support this, both from observations of rates of malignancy associated with these features, and follow-up studies of patients with these adenomas previously removed (see Predicting further development of adenomas).

Cell kinetics in normal epithelium and polyps

The healthy colonic epithelium is characterized by constant cell proliferation and differentiation, resulting in total renewal of the surface epithelial cells about every 3–6 days. The proliferative compartment is situated in the basal third of the crypt. Daughter cells migrate up the crypt and out onto

the surface. As the cells migrate, proliferation ceases, and maturation begins – goblet cells become common [49,50]. The process of cell proliferation, maturation, and death is highly regulated, resulting in a homeostatic balance between production and loss [51].

In adenomas, the normal homeostatic process is disordered. Cell proliferation extends up the crypt. Differentiation is delayed (with fewer goblet cells), and apoptosis is reduced [42,49,52]. This enhanced proliferation and retarded cell maturation results in an increased number of cells. This abnormal cellular load downward infolding of the crypts, which interpose and branch between the normal crypt elements [42,52–54]. Mesenchymal proliferation is also thought to play a role in the formation of adenomas, especially when villous change occurs [53–55]. Although there is still some controversy about the dynamics of adenoma formation, most evidence points to the "bottom up" theory of adenoma formation, from cells situated toward the base of the crypt [56]. Crypt fission is involved in the formation of both types of polyps, but proliferation leads to infolding and the typical sawtooth appearance of hyperplastic polyps [57].

The entire colonic mucosa of patients with adenomas may show increased epithelial cell proliferation, an observation that qualifies epithelial proliferation as a biomarker for neoplasia in the colon [50].

Hereditary factors and adenomas

Hereditary factors obviously play the key role in familial adenomatous polyposis (FAP) and HNPCC [58]; adenoma biology is characteristically disturbed in each condition, and is well characterized at the molecular level (see Chapters 63 and 65). Screening programmes show higher cancer rates in those with a family history of adenomas compared with those without [58,59].

Analysis of family pedigrees in the state of Utah has identified an autosomal dominant pattern of inheritance of adenomas. About 200 members of a large pedigree with familial clustering of colorectal cancer, without evidence of the known inherited syndromes of colorectal cancer, were systematically examined by flexible sigmoidoscopy [60]. Twenty-one percent of family members, but only 9% of spouses, were found to have one or more adenomas. In comparison, hyperplastic polyps were found in 24% of family members and 29% of spouses [60,61]. It was found that an autosomal dominant inheritance of susceptibility to adenoma (and colorectal carcinoma) best explained the pattern of adenoma and carcinoma occurrence in the pedigrees [60–62]. In addition, the gene frequency was estimated to be 19% in that population. Subsequent analyses of additional pedigrees of colorectal cancer patients continue to demonstrate a two-fold to three-fold increase in adenomas in family members compared with spouse controls [58,61–64].

Considered together, these results suggest that familial or hereditary factors may play a role, perhaps as much as 30%, in the causation of adenomas [58,60–64]. If it is the adenoma rather than cancer that signals the inherited risk then there are substantial implications for screening based on family history and the complexity, cost, and magnitude of these programs will increase dramatically as adenomas are so common. Some authorities, but not all, advocate such screening. More information is needed on the risk to other family members when an adenoma is detected.

Environmental factors

Epidemiological studies suggest that environmental factors play an important role because worldwide variation in incidence is not fully explained by genetic variations [65]. Diet is probably the most important environmental factor. The major related factors will be discussed.

Obesity

Weight gain is relevant to adenoma occurrence [66,67], as is obesity. Whereas the evidence linking obesity with neoplasia is based on observations on cancer, there is an implied link to adenoma unless the effect is stage specific. Obesity, particularly central obesity, is an independent factor, but not as strong as weight gain per se, for colorectal cancer and adenomas [66–69]. Obesity interacts with other lifestyle variables in a manner that is difficult to disentangle [65].

The 2002 International Agency for Research on Cancer (IARC) report summarizes the relationship of colorectal cancer risk and body mass index (BMI), especially in men, concluding that there is sufficient evidence to support a link between weight gain and cancer of the colon, and certain other types of cancer, but inadequate evidence to show that intentional weight loss reduces cancer risk for any site [69]. The report also concluded that regular physical activity reduces the risk of colorectal cancer, independently of weight control.

The American Cancer Society Cohort Study of over 900 000 adults identified relative risks of cancer death in the morbidly obese compared with those of normal weight of 1.52 (confidence interval [CI] 1.13–2.05) for men and 1.62 (CI 1.40–1.87) for women. There was also a significant association between BMI and death rates for both colon cancer and rectal cancer [70]. In a Canadian prospective study, the greater risk associated with obesity was found mainly in premenopausal women [71]. Intentional weight loss was associated with a reduction in colorectal cancer risk [68,72].

Physical activity

The evidence that physical activity protects against colorectal cancer is strong but varies by site in the bowel. It is strongest for colonic rather than rectal cancer, again with inferred importance for adenomas. Some of these studies showed statistical benefit restricted to one gender, specific age ranges, intense but not moderate levels of exercise, or only with one of either recreational or occupational exercise categories [66].

Levels of activity needed to protect against colon cancer are 30–60 minutes per day of moderate to vigorous physical activity, and the relationship is dose-dependent [72,73]. Physical activity (> 2 h/week) protects against advanced adenomas more than nonadvanced adenomas, suggesting stage-specific effects [74]. Confirmatory studies suggest physical activity can modify adenoma risk except in the severely obese [75]. In a colonoscopy controlled case–control study, the odds ratio was lowest when physical activity was combined with low waist:hip measurement ratio [76].

Various mechanistic hypotheses are postulated. These include reduced bile acid secretion, stimulation of intestinal transit, immune and hormonal changes, and a reduction in levels of insulin-like growth factor (IGF, trophic to the colonic mucosa) [66,77,78].

Alcohol

With some exceptions, total alcohol intake is more consistently associated with risk for colorectal cancer than specific types of alcoholic beverages [79]. In cohort studies, significant associations between alcohol intake and risk have been found in four of five colon cancer studies; three of three rectal cancer studies; and two of three studies of colorectal cancer (subsite not distinguished) [65]. A US cohort study of men showed a particularly strong association of alcohol intake with the development of colorectal cancer and adenomas in individuals with low folate or methionine intakes [80].

In case–control studies, significant associations between alcohol intake and increased risk have been found in 9 of 18 studies of colon cancer and 9 of 17 studies for rectal cancer [65]. This effect is generally stronger in men than women. Australian studies have found a similar positive association with beer drinking in men [81,82].

A pooled analysis of eight cohort studies reports a modest increase in risk for colorectal cancer with consumption of three or more drinks per day (relative risk [RR] 1.41, CI 1.16–1.72), a risk that was not site specific within the large bowel [79]. In a French case–control study heavy drinking was also related to advanced adenomas [83]. Direct observation of alcohol intake on adenoma growth in vivo showed a low effect at low alcohol intakes over 3 years [84].

Colorectal adenomas, especially advanced adenomas, also are related to high alcohol intake [83]. There may be a particular risk for adenomas in people with certain alcohol dehydrogenase genotypes [85].

Tobacco smoking

Of 51 case–control or cohort studies of colorectal cancer, 22 show a 50% increase in risk from tobacco smoking, and 10 out of these 22 are statistically significant. The evidence is stronger for rectal than colonic cancer, and risk is increased for those who have smoked for a longer period [86,87]. Data are even more consistent for adenomas, with 22 of 27 case–control or cohort studies showing at least a 50% increase in risk. Nineteen are significant and 9 of 10 have a positive dose response [66]. Thus, the main effect of smoking seems to occur early in the process, during adenoma formation, and applies especially to distal sites in the large bowel [88]. Smoking is also recognizable as a risk factor in vegetarians [89].

Smoking may cause specific mutations [90] and may induce activation of CYP1A2 enzymes in the liver to metabolize heterocyclic amines to mutagenic substances [91], particularly with reference to cancers progressing through the microsatellite unstable pathway [92].

Energy intake

Case–control studies consistently show a positive association between energy intake and colorectal cancer risk. As fat intake is closely associated with energy intake, it has been difficult to differentiate between the two [93]. A metaanalysis of 13 case–control studies of diet and colorectal cancer found little evidence of an energy-independent effect on risk of either total or saturated fat intake [94].

A role for insulin or IGF-1 as an endogenous hormone trophic to colorectal neoplastic lesions has been suggested. Epidemiological studies provide mixed evidence to support this. The Women's Health Study of 39 876 health professionals reported a positive association (RR 2.85, 95% CI 1.40–5.80) for dietary glycemic load ($P = 0.004$ for trend across quintiles), supporting this hypothesis [95]. The PLCO (Prostate, Lung, Colorectal and Ovarian) Cancer Screening study has also found an association with IGF-1 and insulin for all adenomas and advanced adenomas [78]. Total carbohydrate intake was also significantly related (RR 2.41, CI 1.10–5.27), especially with respect to nonfiber carbohydrate, namely sugar (RR 2.60, CI 1.22–5.54). However, a US prospective cohort study of 49 124 women showed no association between colorectal cancer incidence and glycemic load or total carbohydrate or sugar consumption [96].

Dietary fat

Although multivariate analyses show no energy-independent effect of fat on colorectal cancer risk, direct relationships between adenoma risk and fat intake are evident, and mechanisms of risk appear more plausible relating to fat than energy, although either is possible. Prevalence of colorectal adenomas, as with cancers, has been correlated with high dietary fat intake (animal fat intake greater than 40% of total caloric intake) [97] (Table 63.2). Conversely, dietary fat intake of less than 15% of total caloric intake has been associated with a low frequency of colorectal adenomas and cancers [98–103].

Increased dietary fat has been shown in experimental animals to lead to increased hepatic synthesis and presence in colonic contents of cholesterol and bile acids. Bacterial flora in the colon might convert these sterols into cholesterol metabolites and oxidized bile acids, which have tumor-promoting activity [104]. Higher fecal concentrations of bile

Table 63.2 Values for relative risk for colorectal adenoma in relation to dietary intake

Dietary component	Quantile of intake: Low 1	2	3	4	High 5	95% CI	*P* value for trend
Energy	1.0	0.81	0.69	0.72	0.85	0.54–1.34	NS
Fat, total	1.0	1.99	1.54	2.29	2.29	1.35–3.88	0.003
Animal	1.0	1.48	1.99	1.17	1.97	0.90–2.24	0.03
Saturated	1.0	1.48	1.79	1.62	1.97	1.20–3.22	0.006
Protein, total	1.0	0.70	0.67	0.98	0.88	0.42–1.07	NS
Animal	1.0	0.80	0.89	0.79	1.02	0.65–1.60	NS

Data relate to a cohort of 7284 males examined within the US Health Professionals Study, 170 of whom had adenomas. Data are adjusted for age, family history of colorectal cancer, and total energy intake.
CI, confidence interval.
Data adapted from Giovannucci et al. [97].

acids and oxidized bile acids have been found in populations at greater risk for colorectal adenomas and cancers, compared with those at lower risk. Subjects living in areas with a high prevalence of colorectal adenomas have greater concentrations of fecal bile acids. Similarly, subjects in these geographical areas have been found to have higher numbers of fecal anaerobic bacteria. There is also an association between high numbers of fecal anaerobic bacteria, increased amounts of metabolized cholesterol and oxidized bile acids in the feces, and the high prevalence of colorectal neoplasms in different populations [104,105]. Oxidation seems a critical step, and efforts to reduce, scavenge, or correct for oxidative damage and free radical production have been proposed, but to date have not proved to be useful preventive measures. A likely exception to the relationship between dietary fat and colorectal cancer risk concerns fish oil. Intakes of fish and fish oil correlate inversely with colorectal cancer incidence [101–106]. Fish oil consumption (rich in omega-3 fatty acids) has been shown to reduce rectal epithelial proliferation [101–107]. Studies supporting this protection include a large endoscopy-controlled study showing a trend for an inverse association of marine *n*-3 fatty acids and large adenomas [108]. The mechanism may implicate an increase in apoptosis, at least as judged from tissues in the "normal" mucosa of adenoma patients challenged with *n*-3 fatty acids [109].

Dietary fiber

Dietary fiber is a heterogeneous mix of plant-derived components, specifically nonstarch polysaccharides as well as undigested starch polysaccharides and noncarbohydrates that are resistant to digestion in the upper digestive tract; this heterogeneity complicates interpretation of epidemiological data. Nevertheless, subjects consuming diets high in fiber that produce bulky stools tend to have a lower frequency of colorectal adenomas and cancers [97,98,100,102,110]. Case–control studies of dietary fiber and colorectal neoplasia have shown more consistent protection from vegetable than cereal fiber sources, although with a notable exception [102,107,110–114]. However, animal studies focus on the relative solubility of different cereal fibers [115] and support the hypothesis that poorly soluble fibers, such as wheat bran, continue to be fermented throughout the colon, releasing metabolic products of fermentation along its length, including the distal colon, which is the region of greatest risk for colorectal cancer in humans [110]. Among these products are the short-chain fatty acids: acetate, propionate, and butyrate. Apart from altering the pH to a more favorable acidic state, short-chain fatty acids are an important fuel for the colonocyte.

Attention has focused particularly on butyrate, which is capable of inducing a more differentiated phenotype, reducing cell proliferation, inhibiting tumorigenesis, and regulating gene expression by inhibition of histone deacetylase [115,116]. In carefully controlled animal experiments, tumorigenesis is inhibited, with one-third of the protective effect accounted for by the measured stool parameters of fecal pH and butyrate production [117]. Butyrate also induces apoptosis in vitro in colon cancer cell lines by activating the caspase cascade [118] and blocks the cell cycle.

The role of dietary polysaccharides has been comprehensively reviewed [119]. It was concluded that the case for their protective effect remained strong but still unproven in intervention trials, probably due largely to issues of trial design and end points. Pooled analyses of prospective trials show a protective effect, and the largest contemporary prospective cohort study (the European EPIC study) also shows protection for both colon and rectal cancer [120,121].

Table 63.3 Recurrence of adenomas ≥ 1 cm at 2 and 4 years of follow-up in the Australian Polyp Prevention Project

Intervention		Adenoma recurrence (≥ 1 cm, number of patients)			
		1-year follow-up		4-year follow-up	
Bran	Low-fat	Absent	Present	Absent	Present
No	No	93	6	74	6
No	Yes	93	5	72	4
Yes	No	89	7	66	7
Yes	Yes	97	0*	75	0[a]

a Significant reduction ($P \leq 0.03$) compared with the groups consuming high-fat diets or no added bran.
Results are shown only for subjects randomized to low-fat or wheat-bran interventions.
Data adapted from MacLennan et al. [123].

Several of the critically reviewed randomized controlled trials will be briefly mentioned here. A study in New York of patients with FAP showed that wheat bran reduced adenoma formation in compliers, although not when analyzed on an intention-to-treat basis [122]. The Australian Polyp Prevention Project [123] was a factorial randomized controlled trial in 424 subjects with recently removed adenomas, testing the effect of a low-fat diet (< 25% energy as fat, red meat retained), a 25-g fine-particle *unprocessed* wheat-bran supplement, and a 20-mg capsule of β-carotene on adenoma occurrence at 4 years. None of the subjects randomized to the combination of low fat and wheat bran developed adenomas more than 9 mm in size, a result that was significant ($P < 0.03$) at both 2 and 4 years (Table 63.3). Although the proportion of patients with large adenomas was not the primary outcome parameter used to establish the sample size in the Australian Polyp Prevention Project, adenoma size was always considered an important outcome variable. Furthermore, pathological [46], epidemiological, anatomical [21,22], and molecular biological [41,124] considerations all point to the importance of large adenomas in the pathogenesis of colorectal cancer. The study demonstrated the feasibility of compliance with dietary change in a high-risk group of patients (those with a history of adenomas).

A larger randomized controlled trial testing 13.5 g of *processed* wheat-bran fiber vs placebo bran, not associated with fat reduction, showed no effect on adenoma recurrence of any size [124]. The National Cancer Institute Polyp Study also yielded a null result with a low-fat diet (< 20% calories as fat) in combination with 3.5 servings per 1000 calories per day when compared with a no-change diet [125]. Neither of those latter studies combined a low-fat diet with *unprocessed* wheat bran supplementation as in the Australian Polyp Prevention Project, but they have been influential in reducing enthusiasm for the preventive effects of dietary fiber.

Resistant starch, by definition, also escapes digestion in the small bowel and may benefit colonic physiology in similar fashion to the nonstarch polysaccharides [119,126,127]. Resistant starch is being tested in a randomized controlled trial of high-risk individuals in HNPCC families (the CAPP-2 study).

Dietary carcinogens

Studies have demonstrated increased fecal mutagenic activity in the stools of patients at risk for development of colorectal adenomas and cancers [104,128,129]. Whether the increased fecal mutagenic activity is related to dietary fat intake, fecal bile acids, or bacteria is still unclear. One interesting line of investigation relates to metabolic activation of dietary procarcinogens such as heterocyclic amines formed in high-temperature cooking; the risk for adenomas was demonstrable with well-done red meat especially in the distal colon and several heterocyclic amines [130]. Acetylator status has been shown to correlate with risk for colorectal cancers and adenomas [129–131]. Attention has also focused on fecal *N*-nitroso compounds, which are formed in the colon after meat ingestion and which may cause DNA adducts and be mutagenic [132].

Dietary carcinogens may be detoxified by hepatic enzymes (n-acetyl transferase [NAT] 1 and 2), which are themselves polymorphic and have variable activity, thereby providing another explanation of familial risk [133]. Glutathione *S*-transferase *M1* and *T1* genes are also involved in the metabolism of polycyclic aromatic hydrocarbons, carcinogens found in tobacco smoke and the diet [134].

Micronutrients

Studies using antioxidants, such as vitamins A, C, and E and β-carotene, have attempted to decrease the production of mutagens in the stool as a way of decreasing colorectal adenomas and cancers. Antioxidants are an attractive intervention as oxidative damage to DNA is thought to be a common final common pathway of damage induced by many carcinogens. However, randomized controlled trials of these and other antioxidants in subjects with previous adenomas have universally failed to show a reduction in the risk for metachronous adenomas or cancer [122,123,135,136]. However, β-carotene does reduce cell proliferation in the colon [137,138]. This dichotomy highlights the multistage nature of colorectal carcinogenesis, with the opportunity for preventive agents to intercept the process at different stages. Because the actions of dietary agents may be stage specific, the final marker of benefit should be cancer, if this can be demonstrated.

Calcium, perhaps by binding fecal fat, bile acids, and cholesterol, may confer a protective effect [139,140,141]. A meta-analysis of several randomized controlled trials of calcium

supplementation (around 1200 mg of elemental calcium daily) reports a modest but significant effect on adenoma occurrence [140], also supported, although less conclusively, by a rigorous Cochrane review [142]. Calcium (such as in calcium-fortified low-fat dairy products) also reduces cell proliferation in randomized controlled trials and inhibits tumorigenesis in animals [143]. The effect is more evident for supplemental, rather than dietary calcium [144], especially in those replete with vitamin D [145], and may be more important for prevention of large adenomas [146].

Selenium levels in serum and soil have an inverse relationship to adenoma prevalence in case–control studies, and this factor is under active investigation [147,148]. Furthermore, serum selenium levels are inversely related to adenoma development [149,150]. Again, the protection may be greatest against large adenomas [151].

Molecular genetics of adenomas

Multiple alterations in DNA have been noted in adenomas. Chromosomal instability characterized by aneuploidy, tetraploidy, and allelic deletions, and global DNA hypomethylation have been observed in sporadic adenomas and in FAP [124,152–156]. Altered patterns of expression of, or mutations in, oncogenes, such as *FOS*, *MYC*, and *RAS*, and deletions of the *APC* gene [152–154] (see Fig. 63.1) may also be seen. Increasing data from studies of small (2 mm) adenomas highlight the importance of *APC* mutation as the initiating (gate-keeping) event, especially in the chromosomal instability pathway [155,156].

In the microsatellite instability pathway characteristic of HNPCC, replication errors occur during mitosis and mutations occur in other genes, including *TGFβRII*, *MSH6*, and IGF receptor type II [41,156]. Inactivation of promoter regions by methylation (the CpG island methylator phenotype) of tumor suppressor and other genes (*p16*, *THBSI*, E cadherin, and *HPP1*) or mismatch repair genes (*hMLH1* and *MGMT*) is another important molecular mechanism that may be evident in adenomas [41,157]. In the microsatellite instability pathway, *KRAS*, *DCC*, or *p53* are less often involved [158]. Up to 15% of cancers show microsatellite stable (MSI), although only about 1%–5% are due to a germ-line mutation of one of the mismatch repair enzyme loci (*MLH2, MSH1, MSH6, PMS2*). In the balance of microsatellite unstable tumors, mismatch repair deficiency (usually loss of function of *hMLH1*) develops sporadically in the tumor itself as a consequence of silencing of the promoter by methylation. Comprehensive sequential data on genetic changes during adenoma development are still lacking.

A third molecular mechanism, estimated to account for up to 30%–50% of colorectal cancers [39,159], involves silencing by methylation with subsequent loss of expression of genes, including the *HPP1* gene [157], the DNA repair gene O^6-methylguanine DNA methyltransferase (*MGMT*) [160], and the *SLC5A8* gene [161]. Methylation of promoter DNA, characterized by CpG dinucleotides, is a common theme in this pathway, a phenomenon known as CpG-island-methylator phenotype (CIMP) [39]. These changes may relate to progression from small to large hyperplastic polyps through to the serrated adenoma, and ultimately to cancers with variable MSI status [157,162]. This pathway is becoming referred to as the "serrated neoplasia pathway" [163]. It is more common in females, more usually involves proximal tumors, and the cancers are usually mucinous and poorly differentiated. A particular feature of this pathway is an activating mutation in the *BRAF* gene and, in some series, frequent *KRAS* mutations [164]. Interestingly, *BRAF* and *KRAS* mutations in most series are mutually exclusive [165,166]. Other investigators have not shown consistent molecular changes relating to the serrated morphology, indicating a more heterogeneous molecular pathogenesis [167,168]. Expression of *hMLH1* may also be lost in serrated adenomas and even in nondysplastic crypts within such polyps, although this usually leads to microsatellite unstable cancers, often also with mutations in short mononucleotide repeats within their coding regions, for example, *BAX, TGFBR2, IGF2R, MSH3*, and *MSH6* [39]. These are not molecular features of traditional adenomas. This variability might be explained by which gene promotor is methylated: methylation of *MGMT* may predispose to mutations in *KRAS* and *TP53*, and thus chromosomal instability with CIMP-positive MSI or MSI-Low cancers. On the other hand, methylation of *hMLH1* would lead to CIMP-positive MSI-H cancers [39]. The CpG island methylator phenotype (CIMP) may therefore overlap with both pathways.

Molecular changes in hyperplastic polyps

A range of genetic abnormalities has been described in sporadic distal hyperplastic polyps, including oncogenes and tumor suppressor genes, especially abnormalities in *KRAS* and *TGFBR2* and also loss of chromosome 1p. Mutations of *APC*, however, are rare. These changes suggest a need to reevaluate the premalignant status of hyperplastic polyps, which at least on clinical observation are considered unrelated to cancer risk. Correlation of the clinical outcomes and molecular pathology of hyperplastic polyps may teach us further lessons about the pathogenicity of certain accumulated mutations. The morphological correlates of hyperplastic polyps with oncogenic mutations are emerging and should allow colonoscopists to target those hyperplastic polyps developing along the serrated neoplasia pathway. The finding of large right-sided sessile "floppy" polyps on haustral folds (sessile serrated polyps) is one characteristic phenotype with malignant potential [169].

Natural history and the adenoma–carcinoma sequence

It is generally accepted that most colorectal carcinomas arise in one way or another from dysplastic epithelium. The fre-

quency, inevitability, and time course of this neoplastic progression is not clearly defined, as prospective observational studies of adenomas left in patients are unethical. The evidence for the adenoma–carcinoma sequence is thus derived from epidemiological association and morphological, biological, anecdotal, clinical [170], and therapeutic data.

Morphological evidence

If the sequence is correct, adenomas and carcinomas should be closely associated. Some 30%–50% of patients with adenomas have at least one other (synchronous) adenoma [170,171]. Furthermore, having once had an adenoma, the patient's likelihood of a future (metachronous) adenoma is increased [3,171–174]. In those with two or more synchronous cancers, 50%–85% have one or more synchronous adenomas. Adenomas found in those with colorectal carcinoma are more advanced [171,173–175].

If the adenoma–carcinoma sequence is correct, one would expect to find small adenocarcinomas arising within adenomas, but few or no small adenocarcinomas arising de novo. Systematic morphological studies of resected specimens show that when minute adenocarcinomas occur, they are frequently found within adenomas; de novo minute carcinomas are rare [170,174].

The relative frequency of the de novo versus adenoma pathway to cancer development is, however, debated. Japanese investigators claim that a sizable minority of cancers do develop without recognizable adenomatous copathology [175]. Japanese investigators studying Western patients have identified similar phenomena, indicating a need to review this question further in Western societies with high colorectal cancer incidence [176–179].

There is a plethora of reports of "flat adenomas" in Western populations, implying a change in nomenclature rather than epidemiology or pathogenesis [176–181]. Studies using standardized pictures and Western and Japanese colonoscopists show significant interobserver variability in reporting the same polyp. Nevertheless, careful reporting using magnifying colonoscopy and dye spray clearly shows small, flat cancers (with malignant invasion), especially where the central area is depressed [182]. Flat morphology carries greater malignant potential [183], although molecular accompaniments of this have been less evident [184].

If the adenoma–carcinoma sequence is correct, then carcinomas arising within adenomas should gradually increase in size and ultimately replace all the adenomatous elements with carcinoma. Indeed, the frequency of finding adenomatous tissue in a carcinoma varies inversely with the size and extent of invasion of the carcinoma. Associated adenomatous tissue is found in more than 50% of carcinomas with only submucosal invasion, in less than 20% of carcinomas with invasion of the muscularis propria, and in less than 10% of carcinomas with serosal invasion. Furthermore, the proportion of adenomas showing severe dysplasia, which is cytologically tantamount to cancer, is proportional to the size of the adenoma. These observations are founded on extensive experience with large series of adenomatous polyps from many centers, but they were initiated by the studies of Morson [170].

The frequency of finding carcinoma within an adenoma also increases proportionally with increasing size, more severe dysplasia, and greater villous component of the adenoma [170,185,186]. Increasing number of adenomas is associated with increasing risk for future carcinoma [170].

Evidence from progressive genetic changes

Molecular analysis of colorectal neoplasia at all putative stages of development reveals an apparent progressive accumulation of genetic abnormalities [155,156,185] (see Fig. 63.1). In the chromosomal instability pathway, a prevalent molecular genetic finding in the earliest identifiable neoplastic pathology – aberrant crypt foci or microadenomas – is that of mutations in the *KRAS* oncogene. By the time these microadenomas have progressed to a size of 1 cm, about half have *KRAS* gene mutations, primarily in the codon 12 [152–181,183–186]. Mutations or deletions in the tumor suppressor *APC* gene on chromosome 5, which lead to a variety of neoplastic pressures in the cell, including activation of the WNT pathway after translocation of β-catenin from the cell membrane to the nucleus [187], appear to be another early molecular event associated with small adenoma development. These are usually associated with aneupoidy and signal entry into the chromosomal instability pathway [185–189]. A range of other effects on cell biology are related to APC function [190].

About one-third of large adenomas and carcinomas have lost one of their chromosome 5 pair and half have allelic loss of chromosome 18, reflecting progressive genomic instability [156]. Loss of function of the tumor suppressor gene *TP53* on chromosome 17 occurs late in the adenoma stage and seems pivotal to the cancer phenotype [191,192]. See Chapters 63 and 65 for a more detailed discussion.

Not all the molecular carcinogenesis is genomic and some is epigenetic. Silencing of promoters of a range of genes through methylation is frequent and leads to a classification of tumors based on methylation status, that is, CIMP status (see "Molecular genetics of adenomas" above). Methylation occurs as frequently in adenomas as in cancers [193].

Evidence from familial disorders

Familial adenomatous polyposis

The increasing risk for occurrence of colorectal carcinoma with increasing numbers of adenomas is well established in the polyposis syndromes. Classic FAP is characterized by the development of more than 100 adenomas; the risk for colorectal carcinomas is virtually 100% if the colon is not removed. In addition, adenomas precede the appearance of carcinoma by about 5–7 years. Mutations in the *APC* gene

occur constitutionally in FAP, whereas in sporadic colorectal cancers the same gene becomes mutated in the tumor cells (only) [194–197].

Hereditary nonpolyposis colorectal cancer (HNPCC)

In the HNPCC (Lynch) syndromes, carcinomas may arise through small precursor adenomas and flat adenomas [158,182,198]. This progression may occur rapidly, as a result of an accumulation of oncogene mutations or suppressor gene deletions [199]. Thus, the morphological sequence of dysplasia to cancer is retained in the HNPCC pathway, but the molecular pathway is different. There are also subtle differences in pathology: more mucinous tumors at a more proximal location and a more prominent lymphoid reaction with tumor-infiltrating lymphocytes. The hallmark feature of this sequence is MSI due to DNA mismatch repair; the frequency of MSI in adenomas is not yet clear.

The serrated neoplasia pathway and hyperplastic polyposis

The molecular evidence relating to cancer development through this pathway is described above (see "Molecular genetics of adenomas"). Up to 30% of colorectal cancers pass through this pathway [39].

Evidence from clinical observations

The average age at which adenomas develop, 50 years, appears to precede the age of development of colorectal carcinomas, 57 years [171]. Available evidence suggests that progression of adenoma to cancer is the exception rather than the norm. If one compares adenoma prevalence data in autopsy studies (40%–50% prevalence; see "Prevalence" above) with lifetime cumulative incidence of colorectal cancer (about 4%–6% in most Western countries), after allowing for multiplicity of adenomas, it can be deduced that only about 1 in 20 adenomas progresses to malignancy.

In a Norwegian study, small polyps were allowed to remain in situ, tattooed for later localization, and then followed for potential progression. Progression was slow and sometimes regression was observed. A study using serial sigmoidoscopy to follow asymptomatic tattooed rectal polyps smaller than 1 cm (not all of which would have been adenomas) found that over the course of 3–5 years, only 4% of the polyps increased in size, 70% remained unchanged, 8% were smaller, and 18% disappeared spontaneously [200,201]. Studies using serial barium enemas also suggest that most polyps (undefined type) grow slowly, if at all [202,203].

However, progression to cancer has been documented. Adenomas have occasionally been left untreated because of patient noncompliance or technical difficulties; invasive carcinomas have been found to develop at the site of these adenomas [170,185,204]. Follow-up studies of patients who have had polyps smaller than 1 cm in diameter demonstrated on barium enema in the precolonoscopic era, when lesions of that size were not surgically removed, have shown that cancers subsequently developed at this site (15%) or elsewhere in the colon (25%) [204].

Using the available data on the growth rate of adenomas and carcinomas and including information on average age of diagnosis of adenomas by size and level of dysplasia and cancer [170,200], a mathematical model has suggested that for those that grow, it takes 2–3 years for a small adenoma (< 0.5 cm) to grow to 1 cm and another 2–5 years for the 1-cm adenoma to progress to carcinoma [205,206]. Invasion and metastasis probably takes another 2 years, and on average, death occurs 2 years after this. These results, when taken together, suggest that those adenomatous polyps that do enlarge, do so only slowly, and that those most likely to progress to malignancy are those that have reached 1 cm in size.

Evidence from therapy

In a large, uncontrolled study, patients underwent periodic sigmoidoscopies, and all polyps that were found were removed. Most polyps removed were found to be adenomatous. The frequency of carcinomas occurring in a subsequent 7–14-year period was found to be about one-third of the expected rate in an untreated population [207]. This has been confirmed in a retrospective study [208] and in the prospective National Polyp Study [3]. In the study by Murakami et al. [208], risk for subsequent cancer was highest in the patients who had biopsy alone and lowest when polypectomy was performed. In the National Polyp Study, patients underwent colonoscopy and polypectomy on enrollment with repeat colonoscopy at 1 year (in half) and at 3 and 6 years. No symptomatic cancers and five asymptomatic malignant polyps were found after almost 6000 patient-years of follow-up over more than 4 years [3]. This represents a 58%–85% reduction in mortality rate from colorectal cancer, depending on whether the reference population is of average risk or includes adenomatous patients. In a Chinese cohort study including nearly 250 000 participants, rectal cancer incidence was reduced by 31% and mortality by 18% by polypectomy, over a 20-year period of observation [5]. In a study of patients with FAP who had colectomies and ileorectal anastomoses, it was found that periodic removal of adenomas from the rectal stump prevented the subsequent development of rectal carcinoma [171].

Randomized controlled trials demonstrating cancer outcomes in those with adenomas left in situ relative to those who have had polyps removed, will never be done for ethical reasons. This precludes the highest level evidence for the benefit of adenoma detection and removal.

Exceptions in the evidence

There are apparent exceptions to this adenomatous polyp–carcinoma sequence. There are rare reports of small carcinomas developing de novo in apparently nonadenomatous

epithelia [209–211]. Nonpolypoid dysplasia is particularly difficult to detect and manage in ulcerative colitis [212]. The frequency with which this nonpolypoid progression occurs is important because effectiveness of strategies to prevent colorectal cancer through detection and removal of adenomatous polyps will be limited to the proportion that evolve through this pathway, explaining in part the cancers that occur despite close surveillance and polypectomy [182,211,213].

Conclusions

Overall, it would appear from these lines of evidence that most carcinomas arise from polypoid or flat dysplastic change in the colonic epithelium, although different molecular biological pathways may be responsible.

Primary prevention

A 20-fold change in risk for colorectal cancer has been observed in individuals at the extremes of the dietary spectrum [98]. If populations can be convinced to reject unhealthy eating habits and change to a healthier lifestyle, substantial control of colorectal cancer incidence could follow. Unfortunately, the prospect for primary prevention by dietary means has suffered setbacks with the publication of the negative findings in various interventional studies including the Arizona wheat bran trial and the National Cancer Institute study of low-fat plus fresh fruit and vegetables diet [124,125]. Much more work is needed to determine feasible diet-based strategies that can be confidently expected to affect incidence.

The option of chemoprevention, especially by nonsteroidal antiinflammatory drugs, may have benefit and is discussed later (see "Therapy" below).

Signs and symptoms of polyps

Colorectal polyps are usually asymptomatic [214,215]. Most often, the polyps are discovered as an incidental finding during examination for intestinal or nonspecific abdominal complaints or other disorders, or during screening endoscopy. Even in the case of FAP, in which adenomas number in the hundreds to thousands, symptoms occur late or result from development of colorectal carcinomas.

In a report of more than 800 hospitalized patients with colorectal polyps, 32% were found to be asymptomatic [215]. When symptoms occur, they tend to be in patients who have colorectal polyps measuring 1 cm or larger. The most common symptoms are rectal bleeding, both overt and occult, change in bowel habit, abdominal pain, and rectal prolapse. Of course, the association of these with a polyp may be coincidental. Furthermore, symptoms have little correlation with histological status, pathological condition, or location [216].

Histological studies have shown that compared with carcinomas, adenomas tend to have minimal ulceration and an intact lumenal surface. Overt rectal bleeding tends to be intermittent and small in amount, only rarely resulting in anemia, with the exception of FAP [217]. Early studies using measurement of total gastrointestinal bleeding demonstrated that only patients with polyps measuring 1.5 cm or larger had consistently higher amounts of (usually occult) fecal blood loss than healthy control subjects [218]. Subsequent studies, based on measurement of immunoreactive hemoglobin from stool samples, have shown that even people with small adenomas have, as a group, higher fecal hemoglobin levels than normal controls [219].

Less than 20% of patients presenting with frank rectal bleeding are found to have colorectal adenomas as the only obvious pathology. Rectal bleeding, especially of recent onset and in patients older than 40 years of age or those with other risk factors such as family history, should not be ascribed to coexisting hemorrhoids without a thorough evaluation of the anus, colon, and rectum [220].

A syndrome of profuse, watery diarrhea, resulting in massive fluid and electrolyte depletion, has been described for large villous adenomas, especially those located in the distal colon and rectum [221]. Colorectal polyps, especially juvenile polyps, may occasionally undergo autoamputation, resulting in rectal bleeding. The presence of recognizable polyp tissue in the feces is extremely rare [222]. Colocolic intussusception due to large polyps has been found in children [223]. Diffuse, nonspecific abdominal pain has been at times attributed to intussusception, particularly of larger polyps. Rectal prolapse of larger polyps also has been reported.

Physical examination rarely reveals signs of colorectal polyps. A digital examination by an experienced person is important as part of all anorectal and colonic evaluations, especially because flat villous lesions close to the dentate line are easily missed at endoscopy, and the digital examination frequently reveals the diagnosis most easily.

Features of neoplastic polyps

The initial diagnosis is usually made by direct endoscopic visualization of the polyp, which should then undergo biopsy or be removed by polypectomy to determine its histological type. At the time of endoscopic examination, certain morphological features may help classify the polyp, although these features can be misleading [224,225].

Because the chance of malignancy in an adenoma is proportional to the size of the adenoma, its villous component, and the degree of dysplasia, these parameters should be described by the pathologist [191,226]. It also partly determines the risk for future advanced adenomas in that individual, thereby guiding decisions on surveillance.

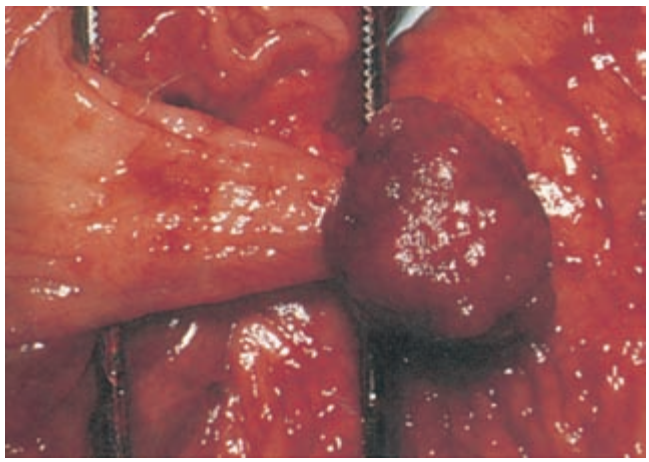

Figure 63.2 Macroscopic appearance of a pedunculated tubular adenoma. The forceps mark the base and the neck of the stalk.

Figure 63.3 A synchronous pedunculated tubular adenoma adjacent to a sessile tubulovillous adenoma. Synchronous adenomas not infrequently are found adjacent to each other. In this instance, a 1-cm pedunculated tubular adenoma is found about 5 cm from a 3-cm sessile tubulovillous adenoma. Note the smooth surface of the tubular adenoma and the smooth, lobulated surface of the tubulovillous, primarily tubular adenoma.

Polypoid adenomas

Tubular adenomas (Figs 63.2 and 63.3) usually are darker red than the surrounding mucosa, have a smooth surface, and tend to be smaller than villous adenomas. Villous adenomas constitute about 5% of all adenomas and occur even more frequently in patients older than 60 years of age [226,227]. When seen during endoscopy, they are usually larger and typically sessile compared with tubular adenomas. The surface has a shaggy, cauliflower-like or frond-like appearance, may be soft and velvety, and is often friable. Villous adenomas tend to be distal in location, large, and bulky.

Tubulovillous adenomas contain at least a 25% villous component and at least a 25% tubular component, without either architectural type predominating. Their clinical behavior tends to be intermediate between that of tubular and villous adenomas [46].

Flat adenomas

Nonpolypoid adenomas, or flat adenomas (localized dysplasia with minimal macroscopic protrusion), tend to be minimally raised (if at all), small (usually < 1 cm) discoid plaques, and they are often erythematous. Because they are not polypoid, they may be missed during colonoscopy [174,178,209,211,227,228]. Judicious use of air insufflation during colonoscopy is needed to detect these lesions because overinflation makes them difficult to detect at colonoscopy. Chromoendoscopy enhances their detection [229].

Despite the small size of these flat adenomas, more than one-third have foci of high-grade dysplasia, especially if centrally depressed [230–233]. In addition, Japanese studies have observed that flat adenomas, when multiple, are often associated with small adenocarcinomas [231,233], although observations in Western studies are less convincing [234].

Serrated adenomas and mixed hyperplastic–adenomatous polyps

Serrated adenomas have the architectural features of hyperplastic polyps but the cytological features of adenomas (dysplasia) [235–238] (Fig. 63.4). They account for less than 1% of colorectal polyps [236]. They are usually polypoid. As noted above, they may be distinguished from sessile, serrated polyps that appear as floppy redundant folds in the right colon, usually having no dysplastic epithelium; these may progress to dysplastic cytology (sometimes referred to as "superficial serrated adenomas") [39,239]. Serrated adenomas are associated with a high frequency of high-grade dysplasia (up to 40%). Mixed hyperplastic–adenomatous polyps show the two types of histology in distinctly separate regions; they should also be treated with caution.

Figure 63.4 Histological section of a serrated adenoma showing intermingling of dysplastic and hyperplastic cytology, the latter being responsible for the serrated appearance at a lower power of magnification. Goblet cell density is highly variable. Typically, the hyperplastic cytology is more prominent toward the surface. Note the substantial architectural disturbance and the great variation in nuclear-to-cytoplasmic ratio between the different types.

Features of nonneoplastic polyps

The nonneoplastic polyps consist of distinct and unrelated groups: simple mucosal, hyperplastic, inflammatory (including pseudopolyps), hamartomatous (including juvenile polyps), and other submucosal polypoid lesions. By definition dysplasia does not occur.

Simple mucosal polyps

Simple mucosal polyps are small, pearl-like excrescences with coloration and appearance similar to adjacent normal mucosa. They are usually smaller than 5 mm, consist of normal colonic mucosa, and have no known clinical significance [46].

Hyperplastic polyps

Hyperplastic polyps are usually small (< 5 mm) and sessile, are found predominantly in the distal colon, and are pale in color. The frequency of hyperplastic polyps appears to increase with age [16]. They are characterized by elongated glands with papillary infolding and increased mucus content (Figs 63.5 and 63.6), which often gives a serrated appearance to the surface of the polyp [43,53,239,240]. The cribriform crypt pattern of adenomas is not usually seen. Such changes may be more easily discerned by using chromoendoscopy. The variant sessile serrated polyp has special molecular significance (see "Hyperplastic polyposis and serrated adenomas" above [39].

Usually, hyperplastic polyps should be removed because one cannot be certain at endoscopy that they are not adenomas [224,225].

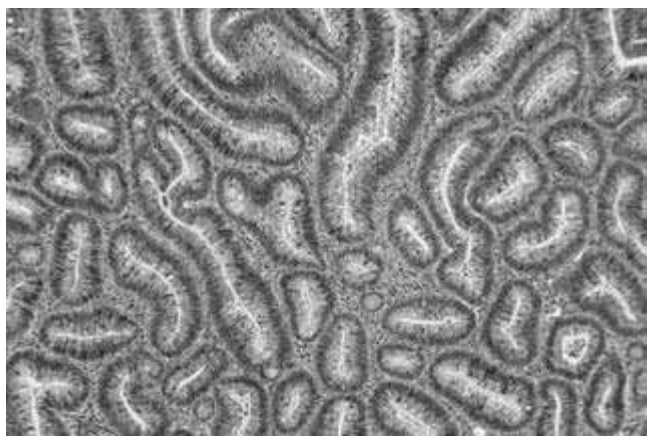

Figure 63.5 Histological appearance of a hyperplastic polyp, characterized by the typical elongated glands with papillary infolding, which produces a serrated surface appearance. The epithelial cells are well differentiated, with abundant cytoplasm, a normal nuclear-to-cytoplasmic ratio, and abundant goblet cells. The nuclei are not hyperchromatic, retain their basal polarity, and show no dysplasia. The starfish appearance of the hyperplastic crypts seen in cross-section is characteristic.

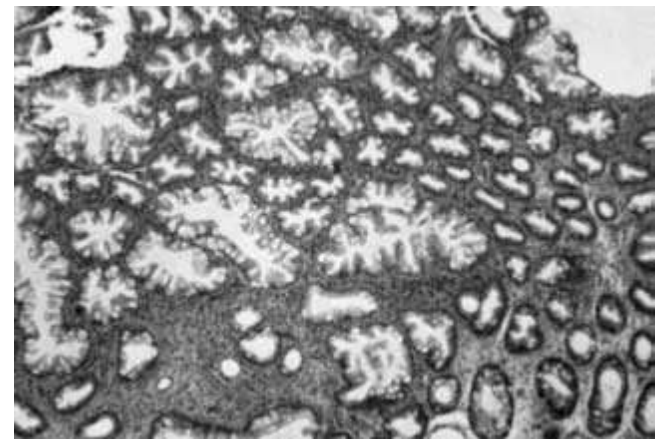

Figure 63.6 Histological appearance of adenomatous epithelium in a predominantly hyperplastic polyp. This polyp should be managed as if it were an adenoma.

Inflammatory polyps

Inflammatory polyps are usually found in the setting of severe inflammatory diseases of the colonic mucosa: ulcerative colitis, Crohn's disease, amebiasis, strongyloidiasis, tuberculosis, solitary rectal ulcer syndrome, ischemic colitis, severe diverticular disease, or schistosomiasis [241]. When a polyp consists of residual islands of intact colonic epithelium in an area denuded of mucosa, the term *pseudopolyp* is often applied. Inflammatory polyps can also consist of exuberant masses of granulation tissue. Inflammatory polyps may be large and solitary, with marked inflammation and ulceration, and can thus appear to be malignant at endoscopy [242–245]. In schistosomiasis, the inflammatory polyp may contain schistosome eggs or adult worms.

Inflammatory polyps may produce symptoms of pain and obstruction [246] and may be pedunculated or filiform. They may occur in settings of minimal inflammation, such as ulcerative colitis in remission, or in a familial setting [247]. Inflammatory polyps must be carefully distinguished from dysplastic mass lesions [243].

The inflammatory "cap" polyp, found in the rectal area, is thought to be a result of mucosal prolapse. It is covered by a cap of inflammatory, hemorrhagic, or granulation tissue. Associated symptoms include mucous diarrhea, tenesmus, and rectal bleeding. Symptoms resolve after polypectomy [248,249]. There have been anecdotal reports of cure following antibiotic therapy, suggesting an infective etiology [250,251]. An unusual inflammatory polyp arising in the anorectal mucosa, and often presenting with rectal bleeding, is the inflammatory cloacogenic polyp [252,253].

Another inflammatory polyp has been termed the *inflammatory myoglandular polyp* because of the presence of inflammatory and granulation tissue in the lamina propria

with abundant smooth muscle proliferation and hyperplastic glands with occasional cystic dilation. When symptoms are present, they consist of overt or occult rectal bleeding [254].

Carcinoma can occur in inflammatory polyps; unusual inflammatory polyps in complex formations should be sampled [243].

Hamartomatous polyps

Juvenile polyps

Juvenile polyps, also known as *retention polyps* because they contain mucin cysts, are so termed because three-fourths of them are found in children younger than 10 years [255,256]. They tend to be single, pedunculated, cherry-red, and round, and possess a smooth surface. They are often friable and ulcerated, bleed frequently, and tend to prolapse because of their pedunculated nature [256–260]. They are also liable to volvulus with resultant ulceration, hemorrhage, autoinfarction, and autoamputation. Histologically, juvenile polyps are hamartomas with distended mucus-filled glands, often with cystic dilation and edematous lamina propria containing abundant vasculature.

Juvenile polyps are rare in the first year of life and are thus presumed to be acquired and not congenital. They occur rarely in the second decade of life but become common again in adulthood. The true prevalence is difficult to determine. In one study, a frequency of about 2% was found in asymptomatic children [261]. In series of children seen for rectal bleeding, 30% had juvenile polyps, with up to half of these being multiple [258,262]. Of all polyps found in children aged under 15 years, up to 97% can be juvenile polyps [257]. Isolated pure juvenile polyps usually are not dysplastic and have no intrinsic malignant potential.

Juvenile polyps also may occur in a familial setting [263,264], with an autosomal dominant pattern of inheritance of polyposis [265] (see Chapter 64). In familial juvenile polyposis, adenomatous and carcinomatous changes are frequent throughout the gastrointestinal tract and in family members [263–270]. Jass [271] has provided guidelines for the diagnosis of juvenile polyposis, describing three criteria:

- more than five juvenile polyps in the large bowel
- juvenile polyps throughout the gastrointestinal tract, or
- any number of juvenile polyps with a family history of juvenile polyposis.

Because solitary juvenile polyps occasionally have associated adenomatous changes, all juvenile polyps should be totally excised. After removal, juvenile polyps recur only infrequently, with a rate of about 3% in 3 years [261]. If extensive adenomatous changes or severe dysplasia are seen, the patient may be considered for surveillance [268–271].

Two genes responsible for familial juvenile polyposis have been reported: the *PTEN* gene [272] and the *SMAD4*/*DPC4* gene [273], on chromosomes 10 and 21, respectively. Another locus, the bone morphogenetic receptor 1A gene (*BMPR1A*), has also been described in juvenile polyposis [274]. About half the families with juvenile polyposis have mutations in one or other of these genes [275].

Peutz–Jeghers polyps

Multiple hamartomatous polyps are found throughout the gastrointestinal tract in Peutz–Jeghers syndrome [276], and usually show prominent branching of smooth muscle. This is a rare autosomal dominant syndrome of gastrointestinal hamartomatous polyposis associated with melanin spots of the lips, buccal mucosa, and extremities [277] (see Chapter 64). Peutz–Jeghers polyps are not considered premalignant, although the syndrome is associated with an increase in carcinomas, mostly extracolonic [278–281]. Syndrome-associated cancers include testicular cancers, breast cancer, and hepatobiliary cancers. Surveillance should be for gastrointestinal polyps, as well as clinical examination of the breast and scrotum. Capsule endoscopy is defining a role for itself in the small bowel surveillance of these familial syndromes, with double-balloon enteroscopy reaching well into the small bowel for polypectomy [282–285]. The genetic locus for Peutz–Jeghers syndrome is the serine-threonine protein kinase gene (*STK11*) on chromosome 19p [285]. Unusual hamartomas with abundant adipose tissue have been described [286,287]. A review of the polyposis syndromes has been published [288].

Submucosal polyps

Submucosal polyps represent elevations of the mucosal surface by submucosal lesions. They are diverse in origin.

Lymphoid hyperplasia

When a focus of diffuse lamina propria lymphocytes becomes hyperplastic, diffuse nodular lymphoid hyperplasia may result [289]. Typically, the normal colonic (or more usually, small intestinal) mucosa is covered with polypoid nodules, generally measuring 5 mm or smaller [289,290]. Discrete lymphoid polyps, which appear pale-yellow or white, may also occur but these do not produce symptoms [291,292]. Diffuse nodular lymphoid hyperplasia occurring in the large bowel needs to be distinguished from FAP; biopsy with histopathological diagnosis is important [292,293]. Familial adenomatous polyposis requires surgery, whereas diffuse nodular lymphoid hyperplasia is usually coincidental and requires no intervention.

Distinguishing between malignant lymphoma and multiple polyps can be difficult [294–296]; lymphoma has developed in a few patients with apparent nodular lymphoid hyperplasia [297,298]. It is unclear whether the malignant lymphoma represents a progression from the lymphoid hyperplasia or a de novo development of lymphoma.

Pneumatosis cystoides intestinalis

Pneumatosis cystoides intestinalis refers to multiple air-filled cysts found within the submucosa of large or small intestine.

The air-filled cysts are easily recognizable by radiographic examination as well as endoscopy. At endoscopy, they are seen as multiple polypoid lesions in the colonic mucosa, which on closer examination appear to be translucent polyps that may look like air blebs just underneath the mucosa. On biopsy, there is often a release of the submucosal air and deflation of the polypoid lesion [299,300].

Pneumatosis intestinalis is generally asymptomatic but can also be associated with pneumoperitoneum [301,302]. Occasional cases associated with scleroderma or chronic obstructive pulmonary disease have been seen [300]. In these cases, the air-filled cysts may resolve after treatment with oxygen [302]. Pneumatosis intestinalis may also complicate ischemia, necrosis, or necrotizing enterocolitis, when it is often fatal [298].

Colitis cystica profunda

Colitis cystica profunda is usually a manifestation of rectal prolapse. The radiographic appearance of colitis cystica profunda is virtually indistinguishable from that of solitary or multiple colonic polyps. The endoscopic appearance can be alarming, mimicking a polypoid cancer. The polyps are sessile and consist of dilated, epithelium-lined mucous cysts within the muscularis mucosae. They are found most often in the rectum in association with inflammatory colitis, or after surgery [303–305]. When seen within an adenoma, colitis cystica profunda has been referred to as *pseudoinvasion, epithelial displacement*, or *misplaced epithelium* [306,307].

Lipomas

Lipomas within the gastrointestinal tract are found most commonly within the colon, usually in the right colon on or near the ileocecal valve. These lesions tend to be solitary but may be multiple in 20% or more of cases. Radiographically, they often show up as slightly radiolucent submucosal lesions. At colonoscopy, they appear yellow with a normal mucosa overlying the polyp continuous with surrounding nonpolypoid mucosa. They are easily identifiable on probing with the biopsy forceps (the "pillow" sign). Polyps with these characteristics need neither biopsy nor polypectomy [308,309].

Other submucosal lesions

A number of other rare submucosal lesions also may present radiographically or endoscopically as polypoid lesions. Biopsies of the surface reveal normal colonic epithelium. Deeper biopsies, or biopsy after submucosal saline injection to elevate the mass, may be required to reach the submucosal mass. Endorectal ultrasonography is particularly useful in diagnosing the origin of a submucosal tumor and whether invasion is present.

Malignant submucosal lesions include carcinoids; metastatic tumors including malignant melanoma and lymphoma; gastric cancer; Kaposi sarcoma; and plasma cell leukemia. Benign lesions include lymphangiomas, fibromas, neurofibromas, leiomyomas, myoblastomas, hemangiomas (including the blue rubber bleb syndrome), and endometriosis [241].

Other colorectal lesions may occasionally masquerade as polyps. Such lesions include hemorrhoids, condylomas, enlarged anal papillae, fibrous anal polyps, inverted diverticula [308], enteroenteric and ureteroenteric anastomoses, and the residual stalk of a pedunculated polyp after polypectomy [241]. Inverted diverticula are important to recognize and not misdiagnose because "polypectomy" can result in perforation. They are rather flat and a little distensible, often with a slight central umbilication.

Diagnosis of adenomas

Colonoscopy is the procedure of choice because of its diagnostic and therapeutic potential. Digital rectal examination is a poor method for diagnosing adenomas except for villous lesions low in the rectum, which may be missed if care is not taken to examine the anorectal region, for example with retroversion of the flexible endoscope. The role of sigmoidoscopy is discussed in Chapter 120. Guaiac or immunochemical fecal occult blood tests are aids to detection as part of a screening program and are discussed in Chapter 62.

Barium enema radiography

Single-contrast barium enema has been shown to have about 75% sensitivity and specificity for detection of polypoid lesions [309,310]; double-contrast (air-contrast) barium enema improves on this [311,312]. Even so, most studies have found that double-contrast barium enemas miss a proportion of polypoid lesions subsequently detected at colonoscopy [311,313,314].

Colonoscopy

When a patient is being assessed for the possibility of having a colorectal neoplasm, colonoscopy is the procedure of choice (see Chapter 120). Colonoscopy allows detection, and either removal of polyps (in most instances) or biopsy. Although colonoscopy carries some risk, the risk is small relative to benefit [314–316]. Polypectomy increases the risk, but is intrinsic to most of the benefit.

Colonoscopy is highly accurate for polyp detection but is not infallible [317–319]. Miss rates for adenomas of any size have been estimated at 17% from studies of paired colonoscopies performed within 120 days [320]. In a back-to-back tandem colonoscopy study, there was a 24% miss rate overall, with 6% of the adenomas larger than 1 cm being missed [12,321]. In a study at St Mark's Hospital, London, colonoscopy and double-contrast barium enema were performed in tandem; 92% of polyps larger than 7 mm were detected at colonoscopy, compared with 74% by double-contrast barium enema [322]. In the dietary polyp prevention trial,

13 cancers in 2079 participants were detected over the intervention period; four were considered as incomplete removal from a preceding polypectomy, and three were considered missed at previous colonoscopy [323]. The sensitivity of colonoscopy for neoplasia is further discussed in Chapter 63.

Computed tomography colonography (virtual colonoscopy)

Studies of CT colonography report widely different accuracies when compared with colonoscopy. The best studies report impressive levels of sensitivity and specificity for adenomas over 1 cm in size and for cancers, and CT colonography can detect polyps missed by colonoscopy [324]. However, experienced radiologists and state-of-the-art software and hardware are all needed to optimize performance, and these are not widely distributed even in Western countries. The better studies do provide a benchmark for performance that is likely to be replicated as better equipment and training diffuse through the radiology community. The value of this procedure is discussed in further detail in Chapter 131.

Biopsy and histopathological examination

Biopsy or polypectomy of a polypoid lesion is essential because histopathological analysis is the definitive diagnostic test. It also informs assessment of future risk. Pathology review with the pathologist [325] is necessary to optimize biopsy and polypectomy procedures including handling of colonoscopically derived specimens. Separate specimen containers should be used when specimens are obtained from different sites, otherwise lesions may be interchanged and it may be difficult or impossible to determine which of several anatomically distinct lesions is the one showing adenomatous changes or malignancy on histological examination. Sampling of every polyp is becoming more important as the patient phenotype is characterized by the number of each specific type of polyp; this information is critical when deciding on which gene to test in a mutational analysis for cancer predisposition. Marking the site of a polyp with sterile india ink may help subsequent localization, especially if surgery is needed for malignancy within a polyp. Alternatively, a metal clip can be attached to the site.

Screening for adenomas

Strategies for screening for colorectal adenoma and cancer are critically presented in Chapter 62. Adenoma detection is important in the context of screening if the goal is to reduce the incidence of cancer. On the other hand, many adenomas are not destined to progress to cancer and the ideal strategy for adenoma detection – that which achieves reliable detection of advanced lesions – is not yet available.

Therapy

Therapy falls into two contexts: treatment of existing lesions and prevention of lesions especially in high-risk settings. Such approaches may be using agents capable of affecting precancer biology, or excisional removal.

Chemoprevention of adenomas

Therapy may be directed at preventing adenoma recurrence in the case of sporadic adenomas or FAP, or at regressing existing adenomas in FAP when removal or resection is not feasible, such as with small duodenal polyps or polyps in retained rectum after colectomy.

The potential value of dietary factors has been discussed under "Primary Prevention" above. At this stage, the most promising agents for chemoprevention are the nonsteroidal antiinflammatory drugs (NSAIDs).

Nonsteroidal antiinflammatory drugs

Most evidence indicates that use of nonsteroidal antiinflammatory drugs, specifically aspirin, is associated with reduced mortality from colorectal cancer [326–331]. Two large trials of aspirin intervention have shown reductions in adenoma occurrence: in one, conducted in patients with previous adenomas, 81 mg (but not 325 mg) aspirin daily (RR 0.81; 95% CI 0.69–0.96) reduced new adenoma occurrence by 19% [332]; the other, in patients with previous colorectal cancer, tested 325 mg aspirin only and also found benefit (RR 065; 95% CI 0.46–0.91) [333]. The dosage discrepancy remains difficult to explain. A Cochrane review has concluded that there is evidence for prevention of adenomas resulting from aspirin use, but not (yet) for cancer prevention, and for incomplete elimination of adenomas in FAP [334]. Pharmacogenomic research suggests that the benefit may be genotypically determined [335]. This effect extends to adenomas, as seen in the Nottingham screening study [329]. Sulindac, a nonselective NSAID, has been shown to be effective in reversing rectal adenoma growth in patients with FAP after ileorectal anastomosis [336–338]. The European CAPP-1 and CAPP-2 trials are evaluating aspirin in randomized controlled trials as therapy for FAP and HNPCC, respectively. The cyclooxygenase 2 (COX-2) selective NSAID celecoxib is effective in FAP [339].

Evidence to date does not support routine chemoprevention with aspirin or sulindac in patients with sporadic (common) adenomas because, while they might be effective, the risk:benefit ratio is unclear. The dose needed to achieve prevention has been estimated from cohort studies to be 600 mg aspirin daily [340]. The risk versus benefit of long-term dosage at this level has not been established, especially in average risk persons.

Inhibition of COX-2 is considered an attractive approach to chemoprevention, as many adenomas express COX-2, espe-

cially if large and distal [341]. Use of rofecoxib and celecoxib for chemoprevention of sporadic adenomas has been confounded by significant cardiovascular and cerebrovascular morbidity and mortality in the active compared with placebo arms of the trials [342], leading to the complete withdrawal of rofecoxib from the market. The situation for celecoxib is under intense debate, but cardiovascular risk was also statistically significant at high doses (800 mg daily) in the large APC chemoprevention trial [343]. Whether this cardiovascular risk exists for all nonaspirin NSAIDs is uncertain. Nevertheless both rofecoxib and celecoxib have been shown to reduce the incidence of metachronous small and large adenomas in the APPROVe and APC trials respectively.

Polypectomy as therapy

Endoscopy and snare polypectomy provide a simple and cost-effective means of managing colorectal polyps [8,344–346]. Cold snare polypectomy or garroting of small polyps is effective [347]. In practice, all polyps should be considered for removal because it is not possible to determine the histological type by their visual appearance. The number of polyps that can safely be removed by polypectomy depends on their location, morphology, and size. In principle, histopathology should be obtained on all polyps. There are two exceptions: multiple polyps (as discussed below) and perhaps where there is the pale, flat morphology typical of hyperplastic polyps in the distal colon [348,349]. In the case of multiple polyps, for practical purposes, at least three of the largest polyps should be removed for confirmatory histological examination [346,347]. The remainder should ideally be subsequently removed if any is found to be an adenoma. However, it should be noted that with this policy, the exact polyp phenotype of the patient will not be ascertainable, and this information may prove critical in any subsequent assessment for genotyping, both with respect to whether it should be done and on which gene to focus. Although hot biopsy [348,349] and bipolar electrocoagulation [350] have been advocated for eradication of diminutive polyps, these techniques can leave behind residual polyp (adenomatous) tissue [351–353] and are potentially dangerous in the thin-walled cecum.

Polyps larger than 1 cm are usually adenomatous and should be removed in toto if pedunculated. If sessile, they may need to be removed piecemeal [354,355]. Histological evaluation of the presence or degree of invasion of any carcinomatous foci is critical because the chance of malignancy increases with increasing size [170]. If there is any concern that residual polyp tissue may have been left, the polypectomy site should be tattooed with sterilized india ink to facilitate follow-up evaluation [356]. This should also be done if there is a high index of suspicion that a polyp may be malignant.

If partially removed polyps are found to be inflammatory, hyperplastic, or otherwise nonadenomatous by histological examination, subsequent complete removal is unnecessary but a sampling of several polyps from each cluster is required.

Multiple polyps require particular care. In patients with newly diagnosed FAP, colectomy, not polypectomy, is indicated. For extensive multiple adenomatous polyps not due to FAP, the colon should be endoscopically cleared of polyps a section at a time to reduce the chance of complications. Note that the thinner wall of the cecal area and right colon requires care when removing polyps by cautery [355,357,358].

Polypectomy is generally safe in adults [315,316] and children [359] when performed by experienced operators. Complications are generally related to polypectomy and the major complication rate is less than 2%. The requirement for hospitalization or surgical intervention (usually as a result of hemorrhage or perforation) is less than 0.3%, and death is rare. Polypectomy should be deferred in patients on anticoagulation and in those with severe bleeding diatheses, unstable cardiac arrhythmias, recent myocardial infarction, acute colitis, pregnancy (second or third trimester), recent colonic surgery, or abdominal abscess or perforation [358]. Some consider that administration of aspirin should cease 1 week before colonoscopy in case polypectomy is required, but others do not; although the issue is unresolved, the risk would appear to be low [360].

Removal of sessile polyps can be assisted by submucosal injection of saline (2–10 ml) to lift the polyp from the muscular wall and minimize the risk for perforation. Kits to facilitate this are commercially available [361,362]. Variations on this technique using sodium hyaluronate to raise the polyp, and needle knife dissection have been developed [363].

The procedural aspects of colonoscopy and polypectomy, including patient preparation, premedication, antibiotic prophylaxis, polypectomy, and polyp retrieval techniques, are discussed in Chapter 126.

Laser ablation and argon plasma coagulation

Ablation with the neodymium : yttrium–aluminum–garnet (Nd : YAG) laser or argon plasma coagulation are alternative methods for the rapid removal of large numbers of small polyps from segments of the colon [364–368]. In experienced hands, these techniques are efficacious, rapid, and relatively safe; complications occur in about 5% of cases [368]. Perforation is rare, but extra care is needed in the thin-walled cecal area [367]. Such ablation should be restricted to the removal of multiple polyps after the histological diagnosis has been confirmed by previous biopsies or polypectomies. Argon plasma coagulation has appeal because the energy can be applied tangentially to the lesion, and the depth of ablation is limited to 3–5 mm, adding a potential increment of safety over lasers. Argon plasma coagulation has been useful for completing removal of large sessile lesions primarily treated with endoscopic mucosal resection [369,370]. The disadvantages are that these methods are destructive, do not yield pathology specimens, and so a focus of invasive malignancy in the polyp could be missed.

Surgical resection

In cases in which a polyp is large and sessile or otherwise cannot be removed by endoscopic polypectomy, surgical resection may be necessary. Surgical resection may also be indicated for those polyps where invasive carcinoma is found (see "Malignant polyps" below) [371–373]. Large rectal adenomas may be extirpated by transanal excision using an operating sigmoidoscope and rigid snare under anesthesia or with an operating microscope in association with a sigmoidoscope. Other large polypoid lesions and malignant polyps need to be removed at laparotomy or by laparoscopy [374]. Once laparotomy is indicated, many surgeons advocate the use of a formal segmental colectomy, including lymph node dissection. The extra resection adds little anesthesia time or perioperative mortality and morbidity [375].

Severe dysplasia and intraepithelial carcinoma

Severe dysplasia and intraepithelial carcinoma are nonmalignant lesions and can be cured by adequate polypectomy. Such change in a polyp is not considered to be cancer because it does not breach the muscularis mucosae. Lymphatics in the colon do not extend beyond the muscularis mucosae into the lamina propria, and hence the possibility of spread is negligible. There have been no confirmed reports of lymphatic invasion resulting from severe dysplasia or intraepithelial carcinoma [185,373–378].

The possibility of progression of severe dysplasia to invasive malignancy demands careful management and complete removal. Evaluation of a polyp removed by fragmental biopsy or piecemeal polypectomy is difficult [45,170,371,375]. The presence of cancerous cells on a biopsy or cytology specimen, without the architectural information provided by a single polypectomy specimen, may not reveal the malignant nature of a polyp.

Malignant polyps

Evaluation of invasiveness comes from careful pathological examination of a completely removed polyp and serial sectioning of it; otherwise, malignancy may be missed [186]. If the neoplastic lesion invades through the muscularis mucosae (with exposure to the lymphatics), the lesion is then termed a *carcinomatous* or *malignant polyp* [377,378].

Misplaced epithelium (pseudoinvasion) may be difficult to distinguish from invasive carcinoma [307,379]. In general, the displaced epithelial cells are surrounded by lamina propria and not by desmoplastic reaction and are similar to the overlying adenomatous epithelium [306,379]. Hemosiderin deposition in the polyp indicates torsion.

The management of malignant polyps remains controversial [344]. This is largely because although the risk of metastasis is small, the studies examining this have also been small. There is general agreement that when a malignant polyp has been identified, poor prognostic features include incomplete polypectomy as judged by the endoscopist or pathologist, poor differentiation on histopathology, and neoplastic cells within 2 mm of the polypectomy margin [380–382]. The presence of venous or lymphatic invasion has been shown to be an independent poor prognostic factor in some series [383–385]. Absence of such risk factors is associated with a low chance of nodal involvement [383,384]. Lymphatic invasion is, however, subject to observer variability [386]. Malignant polyps with venous (or lymphatic) invasion are almost always associated with poor tumour differentiation, but when venous or lymphatic invasion occurs in isolation from the other prognostic variables, they need to be taken into account within the overall context of the patient's comorbidity [387,388].

Controversial prognostic factors are the replacement of the bulk of the adenoma by carcinoma, sessile nature, and large polyp size. Sessile malignant polyps are generally considered to have a worse prognosis, and most usually have other markers of poor risk [389].

Results of removal of malignant polyps

All studies have been small. Of 62 evaluable patients with malignant polyps who had endoscopic polypectomy alone, 4 (7%) had subsequent recurrence [384]. In other studies, patients who underwent endoscopic polypectomy for pedunculated malignant polyps did much better [390]. In a retrospective review of 43 patients with pedunculated malignant polyps who were followed for almost 5 years, 19 patients initially underwent colonic resection, but none from either treatment group had a recurrence [391]. Data indicate that even polypoid carcinomas (where the entire polyp has malignant architecture and cytology) removed by polypectomy do not spread and therefore do not require segmental resection *unless* poor prognostic features are present [392].

Practice recommendations

For the individual patient, it is necessary to weigh the estimated risks of surgery against the risks of leaving residual malignancy in situ after endoscopic polypectomy of a malignant polyp. The presence of poor prognostic features listed above is generally accepted as a reason for surgical resection [45,174,186,380–393], but age of the patient and any coexistent morbidity should always be considered. The decision depends on an estimate of the risk that residual cancer is present compared with the risk for perioperative mortality and morbidity in the individual patient [394]. Operative mortality rates range from 2% to 10% and increase with the age of the patient [373,394]. Because most patients with malignant polyps are in their seventh and eighth decades of life, the risk of colectomy is significant and perhaps greater than the risk of spread.

Based on the evidence [45,186,170,373,392] the following recommendations for management of malignant polyps can be made (Fig. 63.7):

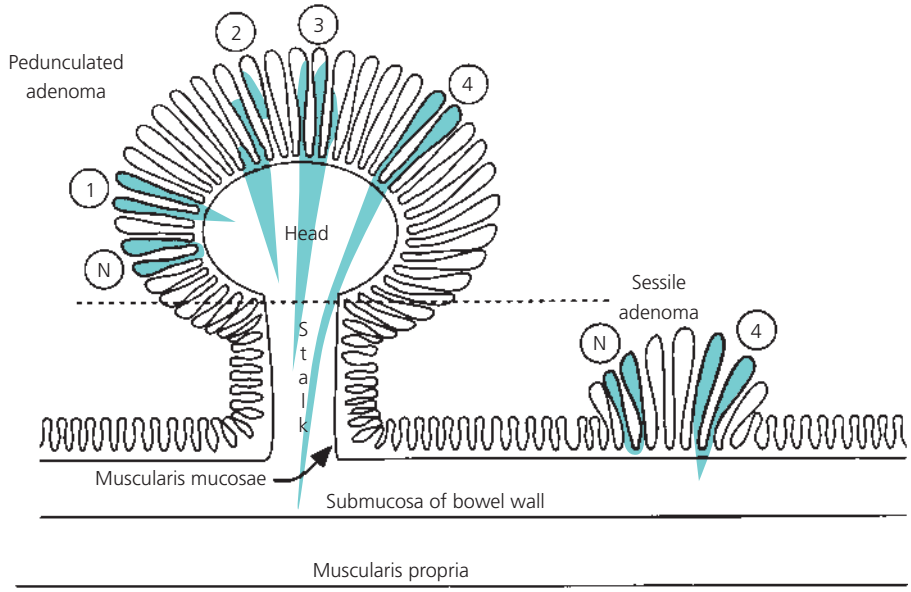

Figure 63.7 Levels of carcinomatous extension in malignant polyps – pedunculated versus sessile adenomas. When carcinomatous cells are contained within the mucosa, without breaching the muscularis mucosae and so extending into the "head" of the stalk, the lesions are known as noninvasive carcinomas, otherwise referred to as severe focal atypia or intramucosal carcinoma (N). Once cancer has invaded through the muscularis mucosae, the polyp is then termed a malignant polyp. Because lymphatics are present in the submucosa, metastatic spread is then possible. Increasing levels of invasion of the carcinoma, to the head (1), neck (2), stalk (3), and base of the stalk or submucosa (4), may carry worsening prognostic implications. A malignant sessile adenoma has, by definition, invaded the submucosa of the bowel wall (4). Lesions with severe dysplasia sometimes described as carcinoma in situ or intraepithelial cancer (N) require no additional therapy after polypectomy. Usually, malignant polyps with invasions only of the head, neck, and stalk (1, 2, 3) and with clear resection margins (at least 2 mm) and no poor prognostic features are adequately treated by polypectomy alone. In malignant polyps with invasion of the submucosa of the bowel wall (4) or with poor prognostic features, colectomy should be seriously considered for potential cure.

- A pedunculated malignant polyp with invasion of the head, neck, or stalk is adequately treated by polypectomy alone if the polypectomy is not piecemeal, is judged completely removed by the endoscopist, the cancer is not poorly differentiated, and the resection margin is free of cancer for 2 mm.
- Malignant polyps with involvement within 2 mm of the margin of resection or with nonassessable margins, polyps with invasion of the submucosa of the bowel wall (especially if there is less than 2 mm margin of clearance), or polyps containing poorly differentiated invasive carcinoma should be treated by surgical resection unless the surgical risk is prohibitive. For sessile malignant polyps, one or more of these criteria are usually present, rendering surgery usually advisable. Blood vessel and lymphatic involvement may influence a decision to perform colectomy.
- Malignant polyps treated by polypectomy alone should be followed by repeat colonoscopy within 3–12 months to assess for recurrence at the polypectomy site.

In all cases, patients must be informed of the rationale behind the physician's therapeutic decision and should participate in that decision.

Follow-up for metachronous adenomas and cancers

Recommendations for following patients with adenomatous polyps vary [344] and several prospective studies are addressing this issue.

Predicting further development of adenomas

In the initial St Mark's Neoplastic Follow-up Study, age, multiplicity of previous adenomas, and size of largest adenoma were independent risk factors for further development of clinically significant adenomas or cancer [395].

These prognostic risk factors for future adenoma occurrence, that is, metachronous adenomas, have been confirmed in colonoscopic follow-up studies such as the US National Polyp Study. In addition to multiplicity (more than two adenomas), the US study also identified family history in association with older age (greater than 60 years) at diagnosis of adenomas as a risk factor for future advanced neoplasms. In Erlangen, the risk for metachronous advanced adenomas was found to relate to parental history of colorectal cancer, entry polyps

with villous or tubulovillous histology, or larger adenomas (> 10 mm) [396].

The US National Polyp Study found that a follow-up interval of 3 years after complete polypectomy for adenomas was as effective as follow-up colonoscopy after 1 year [3]. Longer intervals might be adequate, especially in those patients with small tubular adenomas in the rectosigmoid region [396]. Although definitive data are not available, follow-up intervals extending to 10 years are being recommended for low-risk adenomas [174,344,395,396]. The yield in such patients appears to be less rewarding than in subjects without prior adenomas who are older than 60 years of age [395,397–400].

Rectal epithelial proliferation has been shown in some studies to predict future adenomas [401].

The role of fecal occult blood test (FOBT) in adenoma surveillance remains unclear. However, FOBT is better than no follow-up at all and has been shown to be useful in the intervening years between colonoscopies to maintain contact with patients and aid detection of missed or rapidly developing interval cancers or large adenomas [402].

Predicting future development of cancer

Factors predicting future cancer are similar to those predicting adenoma. In 1618 patients followed for a mean period of 14 years after initial sigmoidoscopy and polypectomy for rectal adenoma, the risk for subsequent rectal cancer depended on adenoma size, histological type, and multiplicity, with a size greater than 1 cm and villous architecture being the strongest risk factors (Table 63.4). Conversely, patients with small tubular rectal adenomas without severe dysplasia had no increased risk for colorectal cancer [174].

Patients who have undergone surgical resection of a primary colorectal cancer are not only at risk for recurrence of their first cancer but also at a three-fold to four-fold increased risk for metachronous adenomas or cancer [173,403,404]. Patients with microsatellite unstable cancers, whether sporadic or HNPCC, are at particularly high risk. Therefore, follow-up should seek not only evidence of metastatic disease and recurrent disease at the surgical anastomosis but also development of a second primary cancer or an adenoma. If the entire length of the colon was not completely visualized before surgery (owing to tumor obstruction or poor preparation), a complete colonoscopy to look for synchronous lesions is indicated after 3–6 months. After the colon has been documented to be free from neoplasms, initial follow-up may be at 3 years, as in the follow-up after polypectomy for adenomatous polyps [405]. Examining the anastomosis for local recurrence in the first 2 years after left-sided cancer is also advisable.

Table 63.4 Risk for colorectal cancer after polypectomy from rectum or sigmoid colon

	Relative risk[a]	95% CI
Single tubular adenoma < 1 cm	0.5	0.4–1.3
Single TVA, VA, or TA > 1 cm	3.4	2.3–4.8
Multiple adenomas	7.7	3.7–14.2

a Risk assessed from 1618 patients at St Mark's Hospital, diagnosed in the precolonoscopy era.
CI, confidence interval; TVA, tubulovillous adenoma; VA, villous adenoma; TA, tubular adenoma.
Data adapted from Atkin et al. [174].

Surveillance recommendations

When a significant adenoma is found (> 10 mm or with villous or tubulovillous histology, or severe dysplasia), surveillance colonoscopy after 3 years suffices provided that the colonoscopist has reasonable confidence that polypectomy is complete and that the entire colon has been cleared of polyps [397,398,405]. The same is appropriate for patients with multiple (> 2) adenomas. If the colon has not been cleared of polyps, colonoscopy should be repeated within 3–6 months to ensure clearance. If the repeat surveillance colonoscopy is clear of adenomas after 3 years, many consider that the interval may be lengthened to 5 years. For patients at higher risk for colorectal cancers, such as those at risk because of HNPCC, more frequent examinations may be in order. However, patients with only small tubular adenomas in the rectum are not at increased risk for colorectal cancer (provided that the adenomas have been removed) and can be dismissed from follow-up or offered repeat examination at 5 or 10 years [174].

Impact of polypectomy on cancer

Polypectomy should reduce the incidence and mortality from colorectal cancer. This has been, to date, difficult to document in national statistics. Trends in colorectal cancer incidence vary around the world, with an upward trend appearing in countries that are adopting a Western lifestyle. Despite the availability of screening and colonoscopic surveillance, the trend continues upward in some countries. One such country is Australia, where the age-adjusted upward trend has been 2% per annum in men and 1% per annum in women between the 1970s and early 1990s [406]. Later data do not show a downward trend. The continuing increase may be due to environmental factors that drive up the incidence despite polypectomy, or may be due to an increase in early diagnosis of cancers ahead of an anticipated later decrease in cancer diagnoses.

In the United States, however, improvements in national mortality statistics and incidence are evident [407]. This improvement is multifactorial, and is a consequence of earlier diagnosis; better surgery, anesthesia, and postoperative care;

Table 63.5 Relative risk for colorectal cancer in subjects undergoing surveillance for adenomas, compared with age- and sex-matched control groups

Study	*n*	Observed	Expected	O/E	95% CI
London [396]	555	4	2.56	1.56	0.43–4.00
Funen, Denmark [409]					
Males	614	6	5.36	1.12	0.41–2.44
Females	442	4	2.60	1.54	0.42–3.94
US National Polyp Study [3]	1422	5	11	0.45	
Japan [208]	206	8	1	8	1.7–78.4
Australia [410]	645	3	3.75	0.8	NS

CI, confidence interval; *n*, number in study; O/E, ratio of observed to expected.

and the impact of adjuvant therapy. The reduction in incidence precedes widescale polypectomy.

Five large-scale adenoma follow-up studies have examined the impact of colonoscopic surveillance on subsequent cancer development [3,5,208,395,409,410] (Table 63.5). The London, Danish, and Australian studies each showed that the incidence of cancer during follow-up was not significantly different from the incidence in age- and sex-matched population controls, implying a reduction from a higher risk if surveillance was not undertaken. Unfortunately, without control groups, the real significance is unclear. The US National Polyp Study demonstrated a statistically significant reduction in risk in participants within the study compared with either population controls or an independent (but historical) population of adenoma patients who did not have colonoscopic follow-up [3]. This is the best study demonstrating effectiveness.

64 Polyposis syndromes

Randall W. Burt, Russell F. Jacoby

Familial adenomatous polyposis, 1640
MUTYH gene-associated polyposis, 1651
Syndromes with hamartomatous polyps, 1653
Polyposis syndromes with neural polyp histology, 1658
Polyposis syndromes of uncertain etiology, 1658
Polyposis syndromes with inflammatory polyps, 1660
Polyposis conditions arising from lymphoid tissue, 1660
Miscellaneous noninherited polyposis syndromes, 1661

The polyposis syndromes are a group of conditions in which multiple gastrointestinal (GI) polyps occur in the lumen of the gut (Table 64.1). Most of these syndromes are inherited, and most exhibit an increased risk for colon cancer. Many benign and malignant extraintestinal manifestations are also observed. The polyposis syndromes have traditionally been categorized according to polyp histology. However, elucidation of the responsible genes has allowed refinement of the categorization as well as a more precise understanding of the pathogenesis, phenotypes, and cancer risks. The clinical importance of the syndromes relates to their inheritance as well as to their benign and malignant manifestations. Cancer prevention is often possible with proper management of patients and their families. The syndromes are also of great importance to biological investigation as understanding of their genetic and molecular etiologies has contributed immensely to the knowledge of cancer pathogenesis and cell biology.

Table 64.1 Polyposis syndromes

Familial adenomatous polyposis (FAP)
Gardner syndrome (GS)
Two-thirds of Turcot syndrome families
Attenuated familial adenomatous polyposis (AFAP)

***MYH* gene-associated polyposis (MAP)**

Syndromes with hamartomatous polyps
Peutz–Jeghers syndrome (PJS)
Juvenile polyposis syndrome (JPS)
Cowden syndrome (CS)
Bannayan–Riley–Ruvalcaba (BRR) syndrome
Hereditary mixed polyposis syndrome (HMPS)
Gorlin syndrome

Polyposis syndromes with neural polyp histology
Neurofibromatosis type I (NFI)
Multiple endocrine neoplasia type IIB (MEN IIB)
Isolated intestinal neurofibromatosis of the colon

Polyposis syndromes of uncertain etiology
Cronkhite–Canada syndrome (CCS)
Hyperplastic polyposis syndrome (HP)

Polyposis syndromes with inflammatory polyps
Inflammatory bowel disease
Devon polyposis
Cap polyposis

Polyposis conditions arising from lymphoid tissue
Nodular lymphoid hyperplasia (NLH)
Multiple lymphomatous polyposis (MLP)
Immunoproliferative small intestinal disease (IPSID)

Miscellaneous noninherited polyposis syndromes
Leiomyomatosis
Lipomatous polyposis
Multiple lymphangiomas
Pneumatosis cystoides intestinalis

Familial adenomatous polyposis (FAP)

Familial adenomatous polyposis (FAP) is the first described, the most common, and the best characterized of the polyposis syndromes. The first reports of FAP appeared in the medical literature in 1861 and 1873 [1,2]. The hereditary nature of this disease was recognized by 1882, and cases of associated malignancy were published in 1887 and 1890. The autosomal dominant inheritance pattern of the disease was clearly established by 1934 [3].

It is known that FAP is an inherited condition characterized by hundreds to thousands of colonic adenomatous

Textbook of Gastroenterology, Fifth Edition Edited by Tadataka Yamada
© 2009 Blackwell Publishing. ISBN: 978-1-405-16911-0

polyps that typically begin to emerge in the second and third decades of life. Colon cancer is inevitable if the colon is not removed. The condition includes Gardner syndrome, about two-thirds of Turcot syndrome families, and attenuated FAP (AFAP). Familial adenomatous polyposis and its variants arise from mutations of the adenomatous polyposis coli (*APC*) gene. Inheritance is autosomal dominant with nearly complete penetrance. Synonymous historical terms for FAP include *adenomatous polyposis coli* and *familial polyposis coli*.

Epidemiology

Estimates of the prevalence of FAP vary from 1 in 6850 to 1 in 31 250 live births (2.29 to 3.2 cases per 100 000 population) [1,4–8]. The frequency is fairly constant throughout the world, with men and women being affected equally. Up to one-third of newly diagnosed cases not belonging to previously identified families appear to represent new mutations [1,9]. About 0.5% of all colon cancer cases historically have arisen in the setting of FAP [4], although the figure may be as low as 0.07%, possibly owing to screening in identified FAP families [5].

Genetics

APC gene

Familial adenomatous polyposis arises from germ-line mutations of the *APC* gene on chromosome 5q21. The *APC* gene is a tumor suppressor gene; thus gene inactivation occurs only after both alleles are mutationally damaged. In FAP, one allele is inherited in a mutated form. Adenoma formation is initiated when the second allele is damaged or lost by a somatic event. The progression from adenoma to carcinoma after *APC* inactivation is similar in both FAP and the sporadic setting, with accumulation of mutations in additional relevant genes, including *KRAS*, *p53*, a gene or genes on chromosome 18, and possibly others [10].

APC gene function

The APC protein is a scaffolding protein that is directly or indirectly involved with a number of cellular functions including cell proliferation, apoptosis, differentiation, adhesion, migration, cell-cycle control, stabilization and assembly of microtubules, and maintenance of cell polarity [10–12]. It is part of the WNT signaling pathway in which activation favors cell growth, suppression of apoptosis, loss of differention, and loss of cell-cycle control. Loss of APC function causes this activation to be constant and unregulated, that is, constitutive. The APC protein also binds to microtubules and can promote microtubule assembly, which is part of the normal mechanism by which colonocytes migrate up the colonic crypt [11,12]. Mutated *APC* thus causes disruption of normal cellular positioning in the crypt, consistent with present models of carcinogenesis. Moreover, APC appears to play a role in cell polarity, which is important for proper cell growth, differentiation, and migration [13,14].

APC mutations in familial adenomatous polyposis

More than 90% of *APC* germ-line mutations that cause FAP give rise to a truncated protein product. The causative mutations (Fig. 64.1) introduce a premature stop codon by nonsense mutations (30%), frameshift mutations (68%), or large deletions (2%) [11]. The actual frequency of large deletions, however, may be as high as 15% because many studies have not included detection methods for large deletions [15–17]. More than 825 germ-line mutations have been found in families with FAP [18], of which over 80% are distinct for each family. The most common germ-line *APC* mutation observed in multiple unrelated families is a 5-bp deletion that results in a frameshift mutation at codon 1309. Although mutations have been found scattered throughout the gene, most are located in the 5′ end of exon 15, often called the *mutation cluster region* [19,20].

The number of colonic adenomas in FAP correlates to some extent with the location of the *APC* germ-line mutation. Profuse or dense polyposis (up to 4000 colonic adenomas) has been reported with mutations in codons 1250–1464, with less dense polyposis proximal and distal to this location [21–23]. Whole gene deletions likewise cause profuse polyposis [24]. As stated previously, the most frequent FAP mutation is at codon 1309. One study found that patients with mutations at that codon presented with symptoms at an average age of 20 years, whereas patients with mutations between codons 168 and 1580, excluding 1309, presented with symptoms on average 10 years later. Certain gene modifiers may also be associated with the severity of polyp expression [25]. Smaller numbers of polyps occur in AFAP, which has been associated with mutations in codons 1–163, 329–338, and 1596–2644 [26]. Disease-causing *APC* mutations are only found in 8.5% of persons with multiple adenomas, defined as 3–100 [27]. A missense *APC* polymorphism, E1317Q, has been postulated to account for some of the remainder of those with multiple adenomas, but this mutation remains of questionable significance [26]. It remains unknown why mutations in certain areas of the gene give rise to AFAP, but there is evidence of functional protein production on the basis of internal translation initiation in AFAP alleles [28].

Correlations have also been found between the locations of the mutations in the *APC* gene and extracolonic manifestations of FAP. Congenital hypertrophy of the retinal pigment epithelium (CHRPE) is observed with mutations between codons 463 and 1387 [29], although mutations between codons 1444 and 1578 are not associated with CHRPE expression [30,31]. Other extracolonic lesions can be found with mutations anywhere in the *APC* gene, but are more common when mutations occur in certain regions of the gene [23,32]. Papillary thyroid cancer is most common with *APC* mutations affecting codons 140–1309 [26]. A higher incidence of desmoid tumors is found with mutations in codons 1445–1580 [26], and in a slightly different region in another

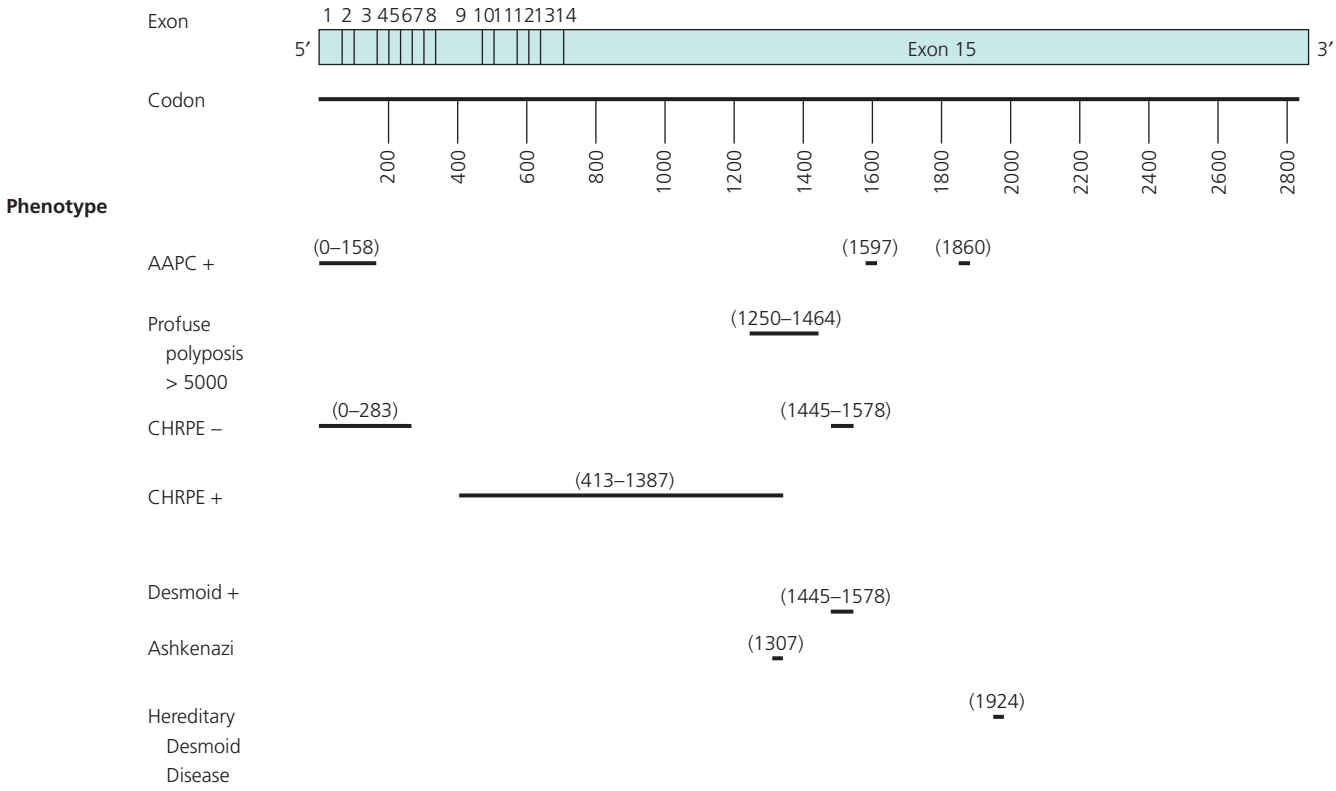

Figure 64.1 Location of disease-causing mutations in the *APC* gene correlated with phenotypic manifestations. Note that thyroid cancer, hepatoblastoma, desmoid tumors, and duodenal adenomas may occur with mutations anywhere in the gene, but are most common in the areas indicated. From Galiatsatos & Foulkes [26], with permission from Blackwell Publishing.

study [33]. Osteomas are more common with mutations beyond codon 1444 [23,31,33]. Hepatoblastoma occurs more frequently with mutations affecting codons 457–1309, whereas duodenal adenomas are more common with mutations between codons 976 and 1067.

A polymorphism of the *APC* gene unique to people of Ashkenazi Jewish descent has also been identified [34]. This polymorphism, I1307K, is present in 6% of Ashkenazi people but in 12% with colon cancer, and in 29% with colon cancer and a family history of colon cancer. It confers an approximate 1.5- to 2-fold increased risk for colon cancer compared with the general population and is believed to cause disease by increasing the mutability of the *APC* allele on which it resides [34–37]. The age of colon cancer onset or adenoma number does not differ in persons with I1307K mutations compared with sporadic cancer and adenomas [38].

Biallelic *MUTYH* gene mutations can give rise to a phenotype that simulates FAP or AFAP, although it more often results in less than 100 adenomatous polyps (see "*MUTYH* gene-associated polyposis" below).

Laboratory genetic testing methods

The laboratory methods used for genetic testing in FAP include protein truncation testing (PTT), gene sequencing, and linkage testing [39–42]. Protein truncation testing is successful in identifying evidence for a disease-causing mutation in 80%–90% of families with clinically defined FAP.

DNA sequencing is more accurate than PTT, with the specific disease-causing mutation being identified in the majority of families with known FAP. Mutations that delete the entire allele or large portions of it will not be detected by DNA sequencing so Southern blotting and multiplex ligation-dependent probe amplification (MLPA) are applied for this purpose [42–44]. Up to 30% of clinically typical FAP patients will not be found to have *APC* mutations by standard methods [45]. In a study of FAP subjects without a disease-causing mutation detectable by standard methods, 14% were found to have large *APC* deletions, 24% had unbalanced allelic mRNA expression of *APC*, 11% had germ-line mutation in other genes, including *AXIN2* and *MUTYH*, whereas 52% remained unexplained [43]. A technique to separate *APC* alleles and test them separately may help further in finding disease-causing mutations [46].

Perhaps the most useful application of genetic testing is mutation-specific testing. Once a specific disease-causing mutation has been identified in an index case in a family, other family members can be tested for the presence or absence of that specific mutation by one of a number of highly accurate

polymerase chain reaction (PCR)-based methods. The accuracy for mutation finding in relatives at this stage is near 100%.

Linkage testing employs DNA markers to track the segregation of a purported mutation through a family. The sensitivity of linkage in identifying genetically affected individuals approaches 99% because of the highly informative markers available. Linkage is limited, however, in that two or three known affected people involving two generations must be available for successful application of the method. Linkage is thus usually applied only when PTT and sequencing fail.

Clinical process of genetic testing

Genetic testing is done on DNA obtained from the white blood cells of peripheral blood. A number of laboratories perform genetic testing for FAP and other inherited conditions. These laboratories can be identified at the GeneTests website (www.genetests.org). Genetic counseling is an essential prelude to genetic testing [47]. Important medical and psychosocial issues surround asymptomatic genetic testing [48–50]. Children's rights and psychological issues are of particular concern when testing of children is being considered [51]. All of these issues must be thoroughly understood by the physician and patient when genetic testing is anticipated. Informed consent for testing is required before testing is done [52]. The physician must either be familiar with the issues or use trained genetic counselors.

There are four settings in which to consider genetic testing for FAP [40–42,53]:

- testing a person with some features of FAP, but where the clinical diagnosis is not certain
- testing a person with clinically defined FAP, but the mutation is not known in the family
- testing relatives in an FAP family once the mutation is known
- embryo testing for preimplantation genetic diagnosis.

The first setting is usually defined as a person with at least 10–20 cumulative adenomas but no known family history of FAP. Finding a mutation confirms the diagnosis of FAP and allows relatives to be tested with high accuracy. Failure to identify a mutation does not rule out FAP, because initial mutation finding is 70% successful at best. Genetic testing in the second situation is similar, but the patient has more than 100 adenomas. Failure to find a mutation means that all close relatives must still be screened as if they have by FAP. In the third setting, relatives of a person with a known APC disease mutation are tested for the presence or absence of that mutation. A positive test indicates the diagnosis of FAP, whereas a negative test (absence of mutation) essentially rules it out. Such individuals then need only average risk screening for colon cancer. The fourth type of testing has been approved in the United Kingdom for prospective biological parents affected by a mutation known to cause FAP [54].

Clinical manifestations

Colonic polyposis

The clinical diagnosis of FAP is made with the presence of at least 100 colonic adenomatous polyps or fewer polyps and an immediate relative with FAP [1] (Figs 64.2 and 64.3). The average number of adenomatous polyps in a person with fully expressed FAP averages 1000, with some people exhibiting more than 5000 polyps. Fewer adenomas are seen early in the development of the disease and in AFAP (see "Attenuated familial adenomatous polyposis" below), with further subdivisions of expected polyp number known to correlate with *APC* mutation location (see "*APC* mutations in familial adenomatous polyposis" above).

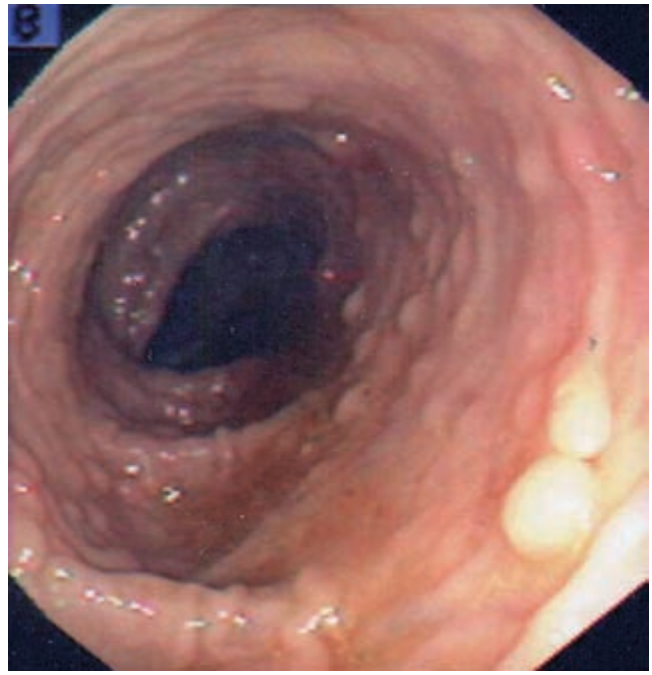

Figure 64.2 Early colonic polyposis in familial adenomatous polyposis.

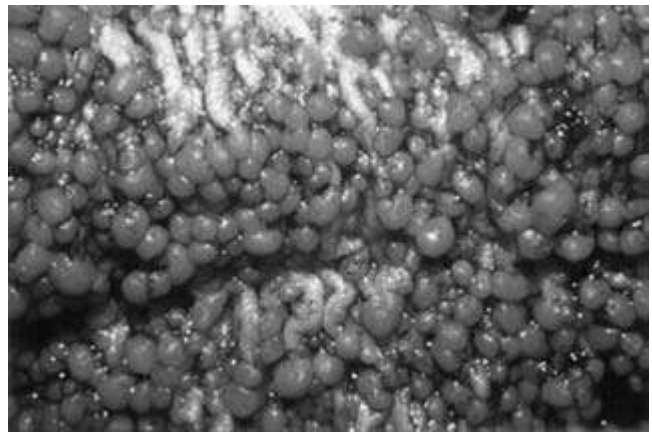

Figure 64.3 Fully developed colonic polyposis in familial adenomatous polyposis. Courtesy of Karen Kim.

Polyps most often begin to appear in the second or third decade of life. The mean age of polyp occurrence assessed by prospective rigid sigmoidoscopy is 15.9 years (range 8–34 years) [55], although occurrence of polyps at younger and older ages has been reported. The average age of FAP diagnosis in patients presenting with symptoms is 35.8 years (range 4–72 years) in the St Marks FAP Registry in London [1]. Similar finding are described in the Danish and Japanese FAP registries [7,8]. The age of symptom presentation correlates with gene mutation location, which, in turn, correlates with colonic polyp density [22,56].

Adenomatous polyps are usually distributed evenly throughout the colon, with a slight excess in the distal colon. The size of the polyps depends on the stage at which the patient is examined. Even in fully developed cases, however, 90% of adenomas are less than 0.5 cm in diameter, and less than 1% of polyps are larger than 1 cm. Polyps may either carpet the colon with myriad small lesions or occur as more distinct and somewhat larger lesions. These patterns appear to have a genetic origin (see "APC mutations in familial adenomatous polyposis" above), although striking heterogeneity of polyp number and growth rate also has been observed [57].

Histopathology demonstrates tubular adenomas, indistinguishable from common or sporadic adenomas. Villous and tubulovillous histologies are also seen, but much less frequently and usually in larger polyps. A histological feature of FAP not observed in the general population is dysplastic or adenomatous epithelial cells in single crypts or even portions of single crypts. These are called *microadenomas* and are often seen in biopsy specimens of normal-appearing flat mucosa [1]. Budding of dysplastic epithelium from normal crypts is also observed. Aberrant crypt foci also have been reported to occur with increased frequency in FAP [58]. These lesions are similar to microadenomas but are identified with methylene blue staining of the colonic mucosal surface.

Colon cancer

Adenocarcinoma is the inevitable consequence of FAP unless the colon is removed. In the St Mark's series, the average age at cancer diagnosis was 39 years. By 45 years of age, 87% had developed cancer, and by 50 years, 93%. Multiple colonic malignancies were present in about 48% of those with cancer (41% synchronous, 7% metachronous). Eighty-four percent of malignancies were at or distal to the splenic flexure, a fraction almost identical to that found in the series of random colorectal malignancies observed by the same authors at that time. Average life expectancy after diagnosis of cancer was 2.6 years. Survival is remarkably improved in relatives of probands who undergo screening [4,59]. Similar observations have been made in other registries [7,8]. Colon cancer has been reported as early as 9 years of age, although the occurrence of malignancy before adolescence is unusual. Polyp number correlates with cancer risk. A study found a 2.3-fold increase in cancer risk at diagnosis for those with more than 1000 colonic polyps compared with those with fewer than 1000 polyps [60]. Each 10-year older age group also exhibited a 2.4-fold increase in cancer risk. There is a 25% incidence of colon cancer in newly diagnosed FAP patients, who remain common because of the high frequency of new mutations [9,61].

Upper gastrointestinal polyps and cancer

Stomach

Gastric polyps occur in 23%–100% of FAP patients [20,62,63] (Fig. 64.4). In the gastric fundus and body, the polyps are most often fundic gland polyps, considered hamartomas. These polyps are histologically seen to consist of simple hyperplasia of the fundic glands with microcysts. Endoscopically, the polyps are multiple sessile lesions, 1–5 mm in diameter, and the same color as surrounding mucosa. They are sessile, hemispherical elevations, occasionally with the appearance of a "waist" but not a stalk [64]. At endoscopic biopsy the polyps usually "chunk off" or detach entirely at the base, unlike other gastric polyps. Considerable variation in size and number is observed. The polyps are sometimes so numerous that they coalesce, forming areas of irregular, matted surface mucosa. Fundic gland polyps rarely cause symptoms.

Fundic gland polyps have been observed to occur in patients as young as 8 years of age. Size and number may gradually increase, remain static, or even decrease. Although they are considered nonneoplastic, fundic gland polyps may rarely progress to cancer [65–67]. Furthermore, up to 25% of fundic gland polyps in FAP patients may exhibit dysplasia, and up to 44% of FAP patients with fundic gland polyps may have dysplasia in some of the polyps. Dysplasia sometimes becomes severe and progresses to gastric cancer [65,68,69]. Similar polyps, although usually fewer in number, also are observed in up to 2% of the general population sporadically and sometimes with chronic use of proton pump inhibitors [62]. Sporadic fundic gland polyps arise from mutations of β-catenin, whereas those in FAP arise from *APC* inactivation

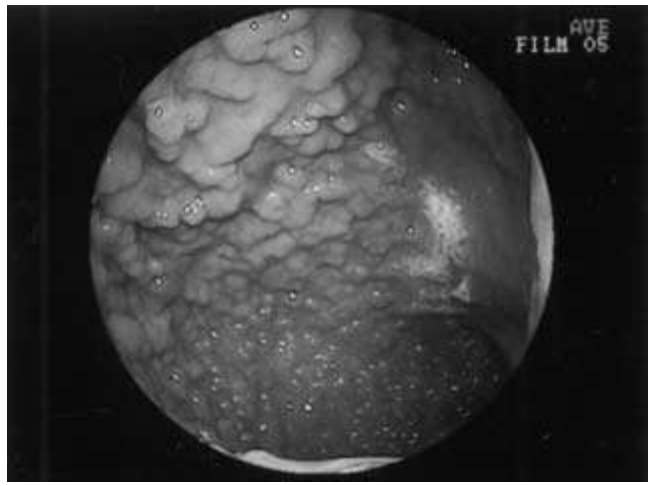

Figure 64.4 Fundic gland polyposis in familial adenomatous polyposis.

[70–72]. *Helicobacter* infection with resultant atrophic gastritis may be protective of fundic gland polyps in FAP [73].

Adenomatous polyps occur in the stomach of about 10% of patients with FAP. They are most often confined to the antrum but are occasionally found in the body and fundus [74,75]. The lifetime risk for gastric cancer in FAP is about 0.6%, believed in part to be from adenomatous polyps.

Duodenum and small bowel

Endoscopically visible duodenal adenomas are found in 50% to more than 90% of FAP patients, and microadenomas are frequently observed [20,63]. The polyps are most commonly 1–5 mm in diameter and multiple. Most patients have numerous small adenomas scattered throughout the duodenum, particularly in the second and third areas, whereas in others the polyps are restricted to the periampullary area. Adenomas may progress, often slowly, and there is evidence of an adenoma–carcinoma sequence similar to that observed in the colon [20]. Adenomas may sometimes grow large, exhibit villous histology and increasing degrees of dysplasia, and may cause symptoms. A scoring system has been developed to evaluate the severity of duodenal polyposis and is widely applied as the Spigelman staging system [76] (Table 64.2). The risk for duodenal cancer increases to 36% within 10 years for Spigelman stage 4 patients [77]. The risk of exhibiting Spigelman stage 4 duodenal polyposis is 43% by age 60 years and 50% by age 70 years [78].

The lifetime risk for duodenal cancer, which most often occurs in the periampullary area, is 3%–5% but in some series has been higher [1,20,63,79]. The age at diagnosis of duodenal cancer ranges from 17 to 81 years, with a mean between 45 and 52 years. Duodenal cancer is one of the leading causes of death in FAP patients who have had prophylactic colectomy.

The presence or severity of duodenal polyposis has been associated with germ-line and somatic mutations between codon 1400 and 1580 [20], although a more proximal mutation region has been suggested in another study [33]. Mutations downstream from codon 1051 have also been assocated with severe periampullary lesions [79]. The frequent clustering of adenomas and cancer in the periampullary area suggests that bile or pancreatic secretions may play a role in carcinogenesis, and a number of mechanisms have been suggested [20,75].

Adenomas may occur throughout the small bowel but are concentrated for the most part in the proximal jejunum (50% of cases) and distal ileum (20% of cases) [80,81]. Malignancy is unusual, but small bowel cancer has been reported. Adenomatous polyps are also known to occur, possibly with increased frequency postoperatively, in the distal ileum after subtotal colectomy, colectomy with ileostomy, and colectomy with ileoanal pull-through. Distal ileal cancer also has been reported in these settings, but it is unusual. Prominent lymphoid polyps may occur frequently in the terminal ileum of younger patients with FAP and should be differentiated from adenomas by biopsy.

Gallbladder, bile ducts, and pancreas

Both adenomatous change and cancer have been reported in the gallbladder, bile ducts, and pancreas [26,80,82–84]. Biliary and pancreatic duct obstruction have arisen from both benign and malignant lesions. The cancer risks are shown in Table 64.3.

Benign extraintestinal growths

Osteomas and dental abnormalities

Multiple osteomas were the first extracolonic lesions to be associated with FAP [1,85,86]. These lesions are benign bone growths found most commonly on the skull and mandible, but they may occur on any bone of the body [87]. The size ranges from imperceptible to several centimeters in diameter, and they number from one to dozens. Osteomas may occur in children who are at risk for FAP before the onset of colonic polyposis [88], but they can continue to occur throughout life [89]. Osteomas have no malignant potential and are not a clinical problem except for occasional cosmetic concern. Subtle radiopaque jaw lesions are often evident by panoramic dental radiographs in patients with FAP and no other apparent extraintestinal lesions of Gardner syndrome

Table 64.2 Duodenal adenomatosis staging system

Polyps	1 Point	2 Points	3 Points
Number	< 4	5–20	> 20
Size	0–4 mm	5–10 mm	> 10 mm
Histology	Tubular	Tubulovillous	Villous
Dysplasia	Mild	Moderate	Severe

Stage I, 4 or fewer points; stage II, 5–6 points; stage III, 7–8 points; stage IV, 9–12 points.

[90,91]. Various dental abnormalities also have been described in FAP, including unerupted teeth, supernumerary teeth, dentigerous cysts, and odontomas [86,88,92,93]. These all may precede the development of colonic polyposis, and the prevalence is estimated at 17%, compared with 1%–2% in the general population.

Cutaneous lesions

Epidermoid cysts, sebaceous cysts, fibromas, and lipomas have all been described as a part of FAP [87,88,94–98]. Epidermoid cysts occur most commonly on the legs, face, scalp, and arms, in that order, but they may appear anywhere on the body surface [96]. They range in size from millimeters to several centimeters. Although common in the general population, they often occur in FAP before puberty, may precede the onset of polyposis, and occur at an average age of 13 years. Fibromas, ranging in size from millimeters to centimeters, are found most commonly on the cutaneous surface of the scalp, shoulders, arms, and back. The cutaneous lesions may cause cosmetic problems, and cysts occasionally become infected.

Desmoid tumors

Desmoid tumors (also called *desmoid fibromatosis*) are benign fibrous growths that occur rarely in the general population (5–6 per 1 million per year [99]) but frequently in FAP, affecting 3.6%–20% of patients [100–103]. About 2% of all desmoids arise in patients with FAP. The relative risk for FAP patients compared with the general population is 825 [104]. The peak incidence of desmoids in FAP is between 28 and 31 years, although desmoids may occur at any age. Independent predictors for desmoids include an *APC* mutation 3′ of codon 1444 (see "Genetics" above), a family history of desmoids, female gender, and the presence of osteomas [33,105]. They most commonly occur following surgery after an average interval of 4.6 years [106]. Desmoid tumors are one of the most common causes of mortality in FAP patients who have had prophylactic colectomy, with a 10%–50% mortality rate from the tumor in those with desmoids. The 10-year survival rate is 63%.

Desmoids may arise in musculoaponeurotic structures throughout the body, although they are most common in the abdomen [102]. They do not metastasize but may infiltrate adjacent structures, extend along facial planes, attach to and erode bones, and engulf and compress blood vessels, nerves, ureters, and other hollow organs of the abdomen. Severe and even fatal clinical problems are sometimes caused by these tumors, especially if mesenteric vessels or other abdominal organs are obstructed. Other complications include bowel perforation, fistulization, bleeding, and ureteral obstruction [100,107]. In the abdomen of FAP patients, mesenteric plaque-like lesions occur that may progress to mesenteric fibromatosis and finally desmoid tumors, often stimulated by surgery [108]. Desmoid tumors usually enlarge gradually and sometimes stop growing altogether. Only about one-third of abdominal desmoids cause pain, although abdominal pain is the most common symptom. Intraabdominal desmoids sometimes become massive, occupying much of the abdominal cavity and encasing many segments of viscera.

These tumors may be the first manifestation of FAP in some patients and families. Furthermore, some families with *APC* mutations exhibit desmoids as their only disease manifestation [109,110]. A distinctive histopathology has been demonstrated in desmoid tumors of young FAP patients, whose first manifestation of the condition was often this lesion [111]. Desmoids in FAP are monoclonal growths of hyperproliferative fibroblastic cells [112]. Excess cell growth appears to occur as a consequence of *APC* gene inactivation and accumulation of β-catenin in the cells [113]. The relationship of desmoids in FAP to sporadic cases is uncertain in view of the distinctive early histopathology [111] and the observation that *APC* gene mutations are uncommon in sporadic desmoids [114].

Congenital hypertrophy of the retinal pigment epithelium (CHRPE)

Multiple and bilateral patches of CHRPE, also called *pigmented ocular fundus lesions*, have been described as a common manifestation of FAP [115]. The lesions are discrete, darkly pigmented, round, oval, or kidney shaped and range in size from 0.1 to 1.0 disc diameters. The presence of bilateral or multiple (more than four) lesions is highly specific (94%–100%) but only moderately sensitive (58%–84%) for FAP [116]. The lesion appears to be congenital, has been detected in a 3-month-old at-risk infant, and may be the earliest clinically detectable lesion of FAP. Careful slit-lamp examination is often required for detection. The presence of CHRPE correlates closely with mutations in specific areas of the *APC* gene (see "Genetics" above).

Adrenal adenomas

Adrenal adenomas have been reported in FAP [117]. Two studies found their occurrence to be significantly higher than in the general population, at 7% and 13%, respectively, versus 3% [118,119]. Several cases of functioning adrenal adenomas and adrenal carcinomas have also been noted in these same series, but any association is uncertain. Most adrenal masses in FAP are found incidentally on computed tomography (CT). It has been recommended that adrenal lesions be managed similarly to those in the general population, which generally entails hormonal investigation if relevant symptoms are present, and needle biopsy if a simple adenoma is not indicated by CT or the lesion is 5 cm or larger [118,119].

Nasopharyngeal angiofibroma

Nasal angiofibromas have been correlated with FAP in a number of patients [120]. The *APC* gene acts as a tumor suppressor gene in nasopharyngeal angiofibromas [121].

Extracolonic malignancies

A number of malignancies outside the colon are known to exhibit an increased lifetime risk in patients with FAP, as shown in Table 64.3. There have been case reports of other rare tumors such as myoepithelial carcinoma and intraductal papillary and mucinous pancreatic tumour [122,123].

The mean age of diagnosis of thyroid cancer is 28 years, ranging from 12 to 62 years [124–126]. A female preponderance is observed, and the histology is predominantly papillary, commonly with a cribriform pattern. Familial aggregation has been observed, and mutation analysis has revealed that most mutations are identified outside the mutation cluster region [126].

Hepatoblastoma exhibits a male predominance and associates somewhat with mutations in the 5′ end of the *APC* gene. This malignancy most often occurs in the first 5 years of life, with some risk up to 15 years of age [127]. The initial presentation of polyposis in a family may be in a young patient with a relatively rare tumor like hepatoblastoma or periampullary adenocarcinoma [128,129].

Syndromes related to familial adenomatous polyposis

Gardner syndrome

In the early 1950s, Gardner and colleagues described a large kindred that exhibited typical FAP, but also prominent extracolonic growths, especially osteomas, epidermoid cysts, and fibromas [86]. All of the other extracolonic lesions noted previously were eventually added to the phenotype of Gardner syndrome. Discovery of the *APC* gene led to the knowledge that FAP and Gardner syndrome arise from mutations of that gene. Further, the expression of extracolonic manifestations correlates to some extent with location of the mutation (see "Genetics" above). The term *Gardner syndrome* is thus mainly of historical interest but will likely continue to be used for families with frequent and obvious extraintestinal manifestations of the condition [32].

Turcot syndrome

Turcot syndrome is characterized by colonic polyposis and central nervous system (CNS) tumors [130]. About two-thirds of Turcot syndrome cases arise from mutations of the *APC* gene and exhibit medulloblastoma-type CNS tumors as well as some anaplastic astrocytomas and ependymomas [131,132]. These cases usually exhibit typical colonic polyposis. The other one-third of cases come from mutations of the mismatch repair genes and are thus a part of hereditary nonpolyposis colorectal cancer (HNPCC). The CNS malignancies in HNPCC-related Turcot syndrome are glioblastoma multiforme tumors, and affected patients also exhibit fewer adenomatous polyps, typical of HNPCC [132]. The risk for cerebellar medulloblastoma in FAP is calculated to be 92 times that of the general population [131]. The occurrence of CNS malignancies is not a completely random event in FAP, however, because 40% of families with brain tumors include more than one affected person. Correlations have not been made between the locations of *APC* mutations and CNS tumors.

Attenuated familial adenomatous polyposis (AFAP)

Attenuated FAP (AFAP), also called attenuated APC, arises from *APC* mutations at either the extreme proximal (5′) region of the *APC* gene, or at the extreme distal (3′) portion of the gene, or in certain parts of exon 9 [133]. Patients with AFAP have many fewer adenomas than those with typical FAP, averaging 25 (range 0–470) in one study and exhibiting a proximal colonic preponderance [133–135]. Equally notable, however, is that the polyp number is extremely variable in many kindreds, with some members of the same kindred having a small number of adenomas and others having numbers approaching that of typical FAP. The cumulative risk of colorectal cancer by age 80 in two large carefully studied kindreds was estimated to be 69%, with an average age at diagnosis of 58 years (range 29–81 years) [133]. In another study, the average age at symptomatic presentation was 52 years [56]. The emergence of adenomas is also delayed by about 10 years. The expression of upper GI polyps, both gastric and duodenal, does not appear to be attenuated in number, age at emergence, or cancer risk [67,135]. It may be difficult to diagnose AFAP without genetic testing because some patients exhibit few adenomas even at advanced ages [133].

Differential diagnosis

All of the polyposis syndromes reviewed in this chapter are included in the differential diagnosis of a patient found to have GI polyposis. Hereditary nonpolyposis colorectal cancer must occasionally also be distinguished, particularly from AFAP [136]. Histology is paramount to specific diagnosis because most of the syndromes have histologically characteristic polyps. The colonoscopic appearance of myriad 1–5-mm polyps is characteristic of FAP, although lymphoid hyperplasia and hyperplastic polyposis (HP) may mimic this appearance. Additional parameters to be considered in differentiating the various polyposis conditions include: polyp distribution throughout the GI tract; polyp number and size; the presence of extraintestinal growths, lesions, or malignancy; and the family history of any of these features. Finally, genetic testing is a powerful tool that can be used to make a definitive syndrome diagnosis in most cases, enabling further genetic testing in family members when the relevant mutation is found. Each of the polyposis syndromes in this chapter is characterized in terms of these parameters. *MUTYH*-associated polyposis (MAP) is often only distinguishable from FAP or AFAP by genetic testing, as many MAP patients present as typical FAP or AFAP. Of note, however, the MAP phenotype consists of multiple to hundreds of adenomatous polyps, but not thousands.

Clinical course and complications

Most individuals with FAP remain asymptomatic until colon cancer occurs. Adenomatous polyp development is slow and insidious. There are usually only a few minute polyps when adenomas are first detected. Polyp number and size increase gradually over ensuing years. Symptoms from the disease are seldom experienced if a timely colectomy is performed. Left untreated, nonspecific symptoms eventually develop from the polyposis or colon cancer. The most common symptoms include rectal bleeding (79%), diarrhea (70%), and abdominal pain (40%) [1]. The average age at onset of symptoms is 32.8 years. Sixty-six percent of individuals who present with symptoms have already developed cancer. Presymptomatic screening and appropriate prophylaxis comprise the favored approach in FAP.

Upper GI polyps are usually asymptomatic unless cancer occurs, with the exception of polyps at the duodenal papilla or in the bile or pancreatic ducts, which may cause obstructive jaundice or pancreatitis. Symptoms from polyps and cancer are nonspecific and include abdominal pain, weight loss, GI blood loss, palpable mass, and lumenal obstruction.

The average life expectancy of patients with untreated FAP has been estimated to be 42 years, but it approaches that of the general population for up to 18 years after colectomy [137]. The major causes of death after colectomy are duodenal cancer (particularly periampullary), desmoid tumors, and rectal cancer if a subtotal colectomy was preformed [138–140]. Other cancers are occasionally observed, such as pancreatic, biliary, adrenal, and small bowel. The cumulative probability of an FAP patient developing extracolonic cancer of any type after colectomy in the St Mark's Registry was found to be 11% by 50 years of age and 52% by 75 years, although most of the malignancies, like in other series, were in the periampullary region [141]. This overall risk was significantly greater than the comparable risk in the general population of about 4% and 22% at ages 50 and 75 years, respectively.

Management

Diagnosis

The diagnosis of FAP is made by:

- finding characteristic clinical manifestations, specifically more than 100 colonic adenomas at any age
- finding adenomas in a younger first-degree relative of a person with known FAP
- finding a disease-causing mutation in the *APC* gene in a person suspected of having FAP [41,42].

Many fewer polyps can give rise to suspicion of AFAP [133]. A constellation of other findings, such as typical upper GI polyps and osteoma, can lead to a high suspicion of FAP. Thus, diagnosis virtually always involves colonoscopic examination with biopsy of the colon and frequently genetic testing.

Screening and surveillance

The primary goal of FAP management is to prevent cancer. In view of the extreme cancer risk in the colon and emerging knowledge of other cancer risks, empirical screening guidelines have been suggested on the basis of these risks and the likely ages of cancer development (Table 64.4).

Colon screening

Colon screening with subsequent surgery has been shown definitively to decrease mortality from large bowel malignancy. A study from the Swedish National Polyposis Registry that included 431 FAP patients from 145 families found a mortality rate of 44% in self-presenting FAP patients compared with 1.9% in relatives who were called up for screening [142]. The Danish Polyposis Registry found colon cancer was diagnosed in 170/252 probands (67%) but only 5/182 screened patients (3%) [59]. Cancer and mortality rates in

Table 64.4 Screening recommendations in familial adenomatous polyposis (FAP)

Cancer	Age to begin screening (years)	Screening interval (years)	Screening procedures
Colon	10–12 Late teens if AFAP	1	Sigmoidoscopy or colonoscopy if AFAP
Duodenal or periampullary	20–25	1–3	EGD also with "sideviewing" exam of the duodenal papilla
Pancreatic (possibly)	20	1–3	Abdominal ultrasound
Thyroid	10–12	1	Physical examination, possibly ultrasound
Gastric	20–25	1–3	Same as for duodenal
Central nervous system, usually cerebellar meduloblastoma (Turcot syndrome)	First decade	1	Annual physical examination, possibly periodic MRI scan of head in affected families
Hepatoblastoma	3 months	3 months	Possibly liver palpation, hepatic ultrasound, α-fetoprotein during first decade of life

AFAP, attenuated familial adenomatous polyposis; EGD, esophagogastroduodenoscopy; MRI, magnetic resonance imaging.

FAP declined dramatically in Denmark after 1975 because screening for polyposis has been successful in leading to colectomy in most patients before cancer could develop [59]. The Finnish polyposis registry found survival in postcolectomy FAP patients who had undergone screening because of a relative with known FAP to be equivalent to that in the general population and statistically much lower than that in FAP patients presenting with symptoms up to 18 years after colectomy [137].

Colon screening should be performed in those with a genetic diagnosis of FAP or in first-degree relatives of those with FAP if genetic testing is uninformative or has not been done. The generally accepted colon screening guideline for typical FAP is annual sigmoidoscopy beginning at 10–12 years of age [39,143,144]. Those initially screened at an older age should probably have colonoscopy for the first examination. If surgery is delayed longer than a year after polyps emerge, annual colonoscopy should be used for surveillance. For AFAP, colonoscopy should always be used for screening in view of the polyp distribution, but can reasonably be delayed until the patient's late teens to mid-20s.

Upper gastrointestinal screening

Upper GI screening has not been demonstrated to improve prognosis but is nonetheless recommended in view of the cancer risk and expectation that mortality can be reduced [63,78,79,145]. The most common recommendation is to begin screening at the age of 20–25 years, although some recommend an initial examination at the time of diagnosis and earlier screening if other family members have exhibited advanced duodenal disease at an earlier age [20]. Standard upper endoscopy should be supplemented with a side-viewing instrument to visualize the duodenal papilla. Endoscopic ultrasound or endoscopic retrograde cholangiopancreatography may also be indicated, depending on endoscopic findings or symptoms. A 1–3-year interval for reexamination is given as follows [20] (see Table 64.2):

- every 3 years for Spigelman stages I and II disease
- every 2 years for stage III disease
- every 6–12 months for stage IV disease.

Another approach is triennial endoscopy if adenomas are not found and annually if they are. It would certainly seem reasonable to examine the stomach during endoscopy and to biopsy any polyps of concern because of size, color, or gross appearance. A pediatric study concluded that all pediatric patients should have upper GI screening at the onset of colonic screening [146].

Screening for other malignancies and desmoids

Screening for the other associated cancers and for desmoids is empirical. The thyroid should be examined annually, starting at age 10–12 years, in view of risk and ease of examination. Some argue that other sites should be evaluated only for symptoms or if these cancers have occurred in relatives. Screening is not performed for desmoids, and evaluation is done only for palpable masses or symptoms. Patients may be given the option of abdominal CT with oral contrast every 3 years to examine the pancreas, small bowel, and adrenal glands, starting at age 20–25 years. Careful questioning is undertaken for CNS symptoms, and periodic magnetic resonance imaging (MRI) of the head is recommended if any family member has had CNS malignancy. Screening pediatric patients for hepatoblastoma is debated but if done should include three-monthly α-fetoprotein determination, liver ultrasound, and liver palpation, probably from birth and continuing throughout the first decade. Specific biliary evaluation is done only for abnormal laboratory tests or symptoms. The small bowel should be examined periodically by radiography or push enteroscopy if upper endoscopy demonstrates severe duodenal polyposis. Capsule endoscopy is also available for small bowel screening [147] but a question remains as to whether the examination is sufficiently complete for larger lesions.

Ileal and rectal screening after colectomy

Adenomas may develop in the ileal pouch after colectomy with ileoanal pull-through surgery, or they may develop from rectal epithelium left with restorative proctocolectomy [148,149]. Whether there is a risk for cancer in ileal pouch adenomas is uncertain, although cases have been reported. Advanced dysplasia and cancer are, however, seen at the anal transition zone, either from rectal tissue unexpectedly remaining with ileoanal anastomosis or from the short segment of rectum remaining with restorative proctocolectomy [150,151]. Screening of the pouch should be done within 2 years after surgery and then every 6 months to 3 years, depending on the presence and number of adenomas.

When subtotal colectomy with ileorectal anastomosis is performed, rectal adenomas often regress [152]. However, they almost always recur, and are associated with a substantial cancer risk [153]. One study of cancer risk in the rectum after subtotal colectomy indicates a 40-year risk of 32% [154]. Chronological age was the only independent risk factor, but cancer was more common when *APC* mutations occurred in gene areas that give rise to dense polyposis. Sigmoidoscopy with ablation of recurrent adenomas is believed to minimize and delay cancer occurrence and is suggested to be done every 3–6 months, depending on the rate of adenoma recurrence [81].

Treatment

Colon and rectum

An appropriately timed colectomy remains the keystone of cancer prevention in FAP. It should be considered once adenomas emerge. Most centers prefer to wait until after the patient has completed high school if colonic adenomatosis remains minimal, although delay has been associated with some cancer occurrence, particularly in FAP patients older than 20 years of age [155]. Surgical options include:

- subtotal colectomy with ileorectal anastomosis
- total colectomy with mucosal proctectomy, ileal pouch construction, and ileoanal pull-through (also known as ileal pouch–anal anastomosis, or IPAA) and restorative proctocolectomy, in which an ileal pouch is also constructed and a 1–2-cm cuff of rectal tissue (the anal transition zone) is left for continence.

The latter procedure is the preferred option in many cases [150]. Colectomy with ileostomy is rarely needed. Subtotal colectomy is a single-stage procedure with slightly less morbidity than the pull-through surgery, but some cancer risk remains and regular follow-up must be assured. This is most commonly done for AFAP and when rectal polyp sparing is present [61,154]. Unfortunately, some cancer risk remains even with the IPAA and restorative proctocolectomy [150,151].

The ileal pouch will fail and require excision or permanent diversion in fewer than 5% of patients after surgery [156,157]. There is a low rate of incontinence in the daytime (5.6%) or nighttime (13.3%), more commonly in older patients [158]. Fecundity is lower in women, but in total only 14% of patients complain of social, sexual, or work restrictions after IPAA [159]. Mesenteric desmoid tumors (MDT) are the principal cause of obstruction and death in FAP patients after colectomy [160]. Laparoscopic restorative proctocolectomy is a minimally invasive technique that aims to reduce the scarring that may trigger MDT, but a 4–7-cm periumbilical incision is still required for vascular dissection and pouch formation [161]. Mutation location may help in determining choice of procedures, but adenoma expression is variable, even with identical mutations, making clinical expression of polyps the determining factor in surgical decisions [56]. Despite rectal screening, the cumulative risk for secondary proctectomy to control polyposis or treat cancer in those with a remaining rectum was 0.70 at 40 years of follow-up in one study, although it was never necessary in patients with AFAP [154].

Some patients with AFAP can be managed for many years with colonoscopic polypectomy of millimeter-sized polyps and may possibly never need colectomy [133]. In general, this approach should only be considered with AFAP patients who exhibit only small numbers of millimeter-sized adenomas. After subtotal colectomy in a large series of patients with AFAP, an average of 3.4 recurrent polyps (range 0–29) and only one rectal cancer was found in the postcolectomy rectal remnant over a mean follow-up of 7.8 years (range 1–34 years) [133].

A number of studies have demonstrated that nonsteroidal antiinflammatory drugs (NSAIDs) and selective cyclooxygenase-2 (COX-2) inhibitors induce colonic adenoma regression in FAP [162–169]. It is presumed but not proven that cancer risk is also diminished. Equally important, polyp ablation is considerably easier in patients with a remaining rectum because NSAID therapy often minimizes the number of new adenomas encountered during follow-up examinations [167]. The use of NSAIDs to prevent the emergence of adenomas in patients with a genetic diagnosis of FAP or to delay colectomy in those with polyposis is not yet recommended [170].

The COX-2 inhibitor rofecoxib (Vioxx) induces polyp regression [168,169] but has been withdrawn from the market because of increased cardiovascular and cerebrovascular events associated with its use [171]. The selective COX-2 inhibitor, celecoxib (Celebrex), has been approved by the US Food and Drug Administration (FDA) and the analogous regulatory agencies in Europe and Japan for polyp regression therapy in FAP patients who have had a subtotal colectomy with a remaining rectum [166]. However, celecoxib has also been found to have similar side effects to refecoxib, but remains available [172]. There are no studies directly comparing celecoxib with sulindac, but sulindac causes anastomotic erosions or ulcerations leading to discontinuation in about half of the patients treated and its efficacy is variable in different studies [167,170]. Interindividual differences in chemopreventive responses are large, and appear to be correlated with the amount of reduction in mucosal prostaglandin levels [173]. Polyp regression has also been reported with use of estrogen/progesterone compounds [174].

Upper gastrointestinal tract

Intervention for gastric polyps is unusual. Discrete adenomas should be endoscopically resected if possible. The development of high-grade dysplasia in multiple fundic gland polyps can lead to the consideration of partial or total gastrectomy.

Duodenal adenomas, particularly ampullary and periampullary ones, more often need therapy [20]. Possible therapies include endoscopic ablation or polypectomy, surgical polypectomy, endoscopic and surgical papillectomy, surgical duodenectomy, and pancreaticoduodenectomy (Whipple procedure) [175]. In view of their malignancy potential, removal of duodenal adenomas should be considered if they become large (probably at least 2 cm) or exhibit villous histology or advanced dysplasia. Single, large, pedunculated adenomas can usually be removed endoscopically, whereas large ones, especially if they are sessile with advanced dysplasia, may require surgical duodenotomy. Severe, diffuse duodenal adenomatosis may require duodenectomy or the Whipple procedure, particularly if severe dysplasia is present. Unexpected cancers are often found in the surgical specimen, although it is still debatable whether radical surgery is appropriate for benign lesions in view of possible complications and morbidity. There is a need for development of more effective chemotherapy for duodenal polyps [175]. The chemopreventive drugs that are effective in the colon – NSAIDs such as sulindac and the COX-2 selective inhibitors celecoxib and rofecoxib – are not as effective in the duodenum and are not FDA-approved for treatment in the small bowel [176]. Ursodeoxycholic acid decreases duodenal adenomas in mice with polyposis, but has not yet been studied in humans [177].

Endoscopic papillectomy is indicated for ampullary adenomas that become symptomatic (including laboratory cholestasis) or develop villous change or advanced dysplasia [20,79,178–181]. The recurrence rate for ampullary adenomas is high, however, and multiple treatment sessions or surgical therapy may be needed in selected cases. The Whipple procedure is most often used if surgery becomes necessary, although an increase in diarrhea often results in patients with previous colectomy [153]. Pylorus-sparing pancreaticoduodenectomy is also an option [182].

The Heidelberg Polyposis Register study is particularly demonstrative of the various options [20]. In that registry, endoscopic follow-up of the duodenum of FAP patients was accomplished in 135 patients, with an average follow-up of 55.6 months (range 6–172 months). One hundred and thirteen of the patients (83.7%) needed no therapy of the duodenum during the follow-up period, whereas 22 (16.3%) did. Endoscopic polypectomies were accomplished in four cases, whereas surgical duodenotomy was needed because of polyp size (large and sessile) in five. Endoscopic papillectomy was done in six cases because of symptomatic adenomas or severe dysplasia. Whipple procedures were needed in seven patients for severe diffuse duodenal adenomatosis, with cancer being unexpectedly found in four of these surgical specimens. Two of these involved the papilla, whereas two were in the distal duodenum.

Other therapies are under investigation for duodenal adenomas, including photodynamic therapy and various NSAIDs. Trials of both have been inconclusive thus far. Studies with higher doses and longer duration of NSAID therapy, or of other drugs such as ursodeoxycholic acid or polyamine analogues, are needed because of the known effect of these agents on colonic adenomas and the need for effective chemoprevention in the duodenum [173].

Desmoid tumors

Magnetic resonance imaging and CT and are equally effective in following desmoid tumors [183]. Treatment is undertaken for symptoms, cosmetic issues, functional disruption, or imminent risk to adjacent structures. Extraabdominal and abdominal wall desmoids are best treated by surgery with adequate resection of margins [100–102]. Less than half of tumors so treated recur, and further therapy with radiation and repeat excision is usually successful. Surgery is difficult, and sometimes impossible, in cases of intraabdominal desmoids but remains as an important option in selected cases [100,184,185].

Because intraabdominal desmoids often involve the mesentery or encase vessels or organs, medical therapies are often first attempted. The most consistent initial therapies for abdominal desmoids appear to be the NSAID sulindac and the antiestrogen tamoxifen. Both give a better than 50% response after 3–6 months of therapy for FAP [186–188]. The response may be even better with a combination of the two drugs. Combination chemotherapy is effective and can be offered for unresectable cases that fail to respond to sulindac and tamoxifen [189–191].

Other therapies have also been used with desmoids with variable success. A combination of low-dose methotrexate and vinblastine demonstrated stabilization of tumor growth or shrinkage in 60% of patients with sporadic desmoids at various stages [99]. This therapy has not yet been reported in FAP desmoid cases. Tyrosine kinase inhibition has also shown some response [192]. Intestinal transplantation has been used successfully in a number of cases of unresectable intraabdominal desmoids [193].

MUTYH gene-associated polyposis

Epidemiology and clinical characteristics

An attenuated polyposis syndrome with a recessive pattern of inheritance has been described involving biallelic mutations in the base excision repair gene *MUTYH*, a gene involved in repair of DNA oxidative damage [194,195]. The clinical condition is characterized by multiple adenomatous polyps and an increased risk for colorectal cancer. Referred to as *MUTYH-associated polyposis* (MAP), the condition is often indistinguishable from classical FAP or AFAP except that the family history will demonstrate recessive inheritance. The inheritance pattern may not be helpful, however, because of the substantial frequency of de novo *APC* germ-line mutations causing FAP, and because many small families will not exhibit a recessive pattern even if MAP is present in the family.

MUTYH-associated polyposis accounts for 7.5%–12.5% of FAP patients in whom a disease-causing *APC* mutation is not found [195,196], and from 16% to 40% of patients with 15–100 colonic adenomas but not FAP [195,197–200]. Patients with MAP do not appear to have more than 500 adenomas but may exhibit only small numbers of adenomas [196,197]. In a study from the Mayo Clinic, biallelic *MUTYH* mutations were not found in any patients with fewer than three adenomas, with a colon cancer diagnosed when over 50 years of age, or with a microsatellite instability (MSI)-positive colon cancer. In the absence of *APC* mutations, biallelic *MUTYH* mutations were found in 1.7% of colorectal cancer patients aged up to 50 years, in 13.6% of patients with 20–49 adenomas, in 20% of patients with 50–99 adenomas, in 20% of patients with 100–499 adenomas, but in no patients with more than 500 adenomas.

MUTYH-associated polyposis appears to be an unusual cause of colon cancer, even early-onset colon cancer [201], but the risk of this malignancy in those who have biallelic *MUTYH* mutations is high. In a study from Finland, 0.4% of 1042 population-based colorectal cancer cases had biallelic *MUTYH* mutations [202]. All those with mutations were found to have adenomas, ranging in number from 3 to 100. In a large (2239 cases, 1845 controls) population-based case–control study from Scotland, 0.8% of colorectal cancer cases aged

under 55 years, and 0.54% of all cases, had biallelic mutations [203]. Biallelic mutation carriers had a 93-fold excess risk of colorectal cancer. Significantly more biallelic carriers exhibited adenomatous polyps, although 36% had no polyps. There was also a slight (1.68-fold) but significant (95% CI 1.07–2.95) increased risk of cancer among heterozygous mutation carriers among patients aged under 55 years, with a population attributable risk of 0.93% (95% CI 0%–2.0%) in this group. A Canadian case–control study with 1238 colorectal cancer cases and 1255 controls found 2.34% of cases and 1.67% of controls to be heterozygous for *MUTYH* mutations [204]. This represents an odds ratio of 1.4 (95% CI 0.8–2.5), so statistical significance was not reached. Thus the cancer risk for biallelic mutation carriers is high, accounts for almost 1% of colon cancer cases, and is usually, but not always, associated with multiple adenomas. There appears to be a slight colorectal cancer risk associated with heterozygous mutation carriers but further investigation is needed to verify this.

MUTYH-associated polyposis syndrome is different from the syndromes of AFAP and FAP, but it is impossible to distinguish from these conditions in individual patients [205]. The similarity of MAP is more with AFAP, in that it presents at later ages, typically mid-50s (but sometimes as young as 16) [205] and exhibits relatively fewer polyps. Polyp numbers from 5 to 750 have been reported, but as studies above demonstrate, many biallelic *MUTYH* mutation carriers have no polyps. Gastric cancer, duodenal adenomas and CHRPE have been reported [205], but uncommonly enough that their association remains unclear. Reported colorectal cancers in MAP have been predominantly left-sided [205].

Genetics and pathophysiology

MUTYH-associated polyposis arises from biallelic inactivation of the *MUTYH* base excision repair gene. The DNA glycosylase encoded by this gene accomplishes DNA oxidative damage repair. Inactivation of the *MUTYH* gene by mutation gives rise to frequent G:C to T:A transversions, which are thought to affect the *APC* gene somatically and thereby give rise to polyp and cancer predisposition [194,195,205]. Predisposition to polyps and cancer occurs with germ-line *MUTYH* mutations, but somatic *MUTYH* mutations do not seem to play a role in the pathogenesis of colon cancer [206]. And although mutations of *APC* are frequent, and *APC* is probably the first mutated gene in *MUTYH*-associated tumor pathogenesis, there appear to be some differences in the molecular pathways involved [207]. A specific and characteristic *KRAS* mutation is frequently observed in MAP adenomas and cancers. Neither microsatellite instability nor chromosomal instability is observed in MAP, but instead a near-diploid karyotype with overall low levels of loss of heterozygosity.

The two most prevalent *MUTYH* mutations, occurring in more than 80% of persons of European ancestry with MAP, are Y165C and G382D [194,195,198,199,202,206]. A population frequency for each of these alleles in the white population has been estimated at 0.005 [194]. An E446X nonsense mutation is found in Indian families [198,199], a 1295delGGA in affected Italian patients [208], a Y90X mutation in Pakistani families [198], and an nt1395–7delGGA in a Greek patient [205]. Mutations other than the common ones sometimes occur on the second allele, thereby causing gene inactivation. Thus in a person undergoing genetic testing, the common mutations are first examined. A diagnosis of MAP is made with the presence of one of the common mutations on each of the alleles. If only one allele is affected by one of the common mutations, sequencing is then done to determine if an inactivating mutation is present on the second allele.

Diagnosis, screening, and treatment

There are no distinguishing clinical or pathological characteristics for MAP. In fact the individual phenotype cannot be distinguished from patients with multiple adenomas, attenuated FAP, or classical FAP. The natural history of adenoma occurrence and progression is not well understood but MAP cancers occur predominantly in the left colon, with stage and grade similar to that observed in sporadic colorectal cancer [205]. Adenomas in MAP are also histologically indistinguishable from sporadic or FAP adenomas. Without further characterization of MAP, likely be accomplished in the near future, genetic testing appears to be the only method to identify accurately this condition.

MUTYH-associated polyposis is sufficiently common among patients with multiple adenomas that any such patient, particularly one with more than 15–20 adenomas, should be considered for a diagnosis of MAP and thus be considered for *MUTYH* genetic testing [196,198,200,202]. Similarly, patients with early-onset colorectal cancer not explained by other genetic syndromes could be considered for *MUTYH* genetic testing [196,202]. Some MAP patients will still be missed with these criteria, and thus family history and other elements of the Bethesda criteria have also been used to identify MAP patients [197]. Finally, those in whom AFAP or classical FAP is being considered, but in whom no *APC* mutations are found, should also have testing for *MUTYH* mutations, particularly if no vertical transmission of colorectal polyps or cancer is apparent. It may, in fact, be more efficient to begin with *MUTYH* testing rather than *APC* testing in multiple adenoma patients with no obvious vertical transmission of disease [200]. The only other known genetic condition possible in this setting is AFAP, which may be less common than MAP.

Surveillance and disease management of the colon should be similar to those performed for patients with multiple adenomas, AFAP, and FAP until further information is available concerning the natural history of MAP [205]. Thus colonoscopy should be used for screening, surveillance, and polyp removal. Colonoscopy intervals of 1–3 years would seem appropriate, depending on the adenoma number and rate of recurrence. If polyps cannot be managed colonoscopically,

or multiple advanced adenomas (> 1 cm, villous histology or severe dysplasia) are encountered, then colectomy should be considered. As with to AFAP, FAP, and some adenoma patients, subtotal colectomy with close subsequent surveillance would seem to be the best option if relative rectal sparing is present, and restorative proctocolectomy undertaken if the rectum is substantially involved. It is not known if upper endoscopic surveillance should be performed. The subset of multiple adenoma patients with MAP might be an attractive group in which to investigate antioxidant therapy as a preventive option in view of the defective oxidative repair mechanism in MAP.

Syndromes with hamartomatous polyps

Peutz–Jeghers syndrome

Epidemiology and clinical characteristics

Peutz–Jeghers syndrome (PJS) is an autosomal dominantly inherited syndrome of histologically distinctive hamartomatous polyps of the GI tract and characteristic mucocutaneous pigmentation [209]. Its incidence is estimated at 1 in 120 000 births. A high risk for both GI and non-GI cancers is known to be part of this condition [210].

The mucocutaneous melanin pigment spots are seen in more than 95% of cases (Fig. 64.5). They are 1–5 mm in diameter and most commonly occur in the perioral and buccal areas (94%). Pigment spots on the lips are distinctive in that they cross the vermilion border and are often much darker and more densely clustered than common freckles. These spots also occur on the face, forearms, digits, palms, soles, perianal area, and rarely the intestinal mucosa. The pigment appears in infancy and may fade with age, less so on the buccal mucosa.

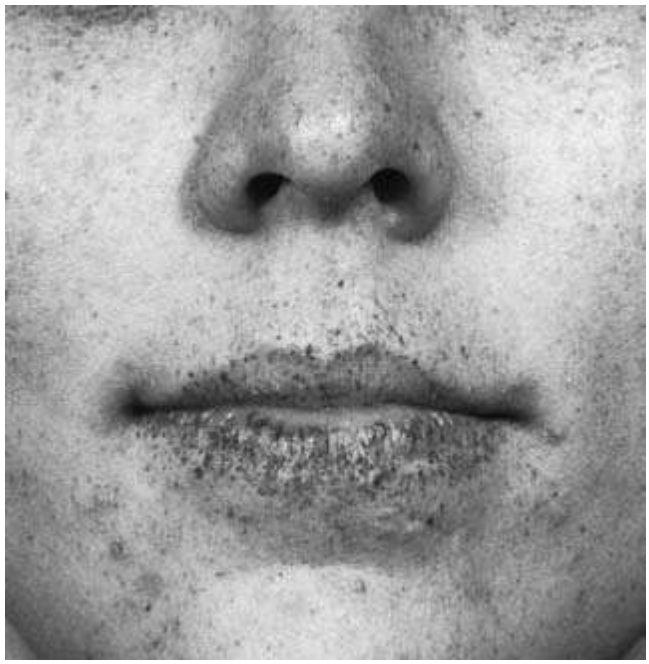

Figure 64.5 Typical perioral melanin pigmentation in Peutz–Jeghers syndrome.

The GI polyps occur in 88%–100% of patients. Their frequency by segment is: stomach, 24%; small bowel, 96%; colon, 27%; and rectum, 24% [211,212]. Between 1 and 20 polyps are usually found per GI segment. Polyps range from 0.1 to 3 cm in diameter and have a coarsely lobulated surface. Polyp growth begins in the first decade of life, but patients typically do not develop symptoms until the second or third decade [213]. Symptoms arise from larger polyps, which may infarct, ulcerate, bleed, and cause intestinal obstruction and intussusception. Peutz–Jeghers polyps are histologically distinct. They are nondysplastic, have normal overlying epithelium specific to the GI site in which they are found, and exhibit an arborizing pattern of growth with muscularis mucosae extending into branching fronds of the polyp. Epithelial infolding may result in what is termed *pseudoinvasion*, which can lead to an incorrect diagnosis of cancer. Adenoma and cancer may occur in Peutz–Jeghers polyps, which exhibit monoclonality, and are thought to be the cause of intestinal cancer in this syndrome [213]. This has been referred to as the hamartoma–adenoma–carcinoma sequence.

Benign complications from the polyps predominate in the first three decades of life. The average age at diagnosis is 22 years in men and 26 years in women [211]. One-third of patients experience symptoms in the first decade of life, and 50%–60% before the age of 20 years. The clinical course of PJS is characterized in many patients by repeated surgeries for complications of small bowel polyps. Malignant complications become the dominant cause of clinical problems after 30 years of age [211], with an average age of 43 years for cancer diagnosis of any type. The malignant risk in PJS includes colorectal, breast, pancreatic, gynecological, small bowel, lung, and gastroesophageal cancers in that order of risk [210]. The overall risk of developing cancer at ages 20, 30, 40, 50, 60, and 70 years, is 1%, 3%, 19%, 32%, 63%, and 81%, respectively. The combined risk for gastroesophageal, small bowel, colorectal, and pancreatic cancers at 20, 30, 40, and 60 years is 1%, 10%, 18%, and 42%, respectively. Individual site cancer risks are given in Table 64.5, along with screening recommendations.

Distinctive tumors in women with this condition include ovarian sex cord tumors with annular tubules (SCTAT) (which are benign although approximately 20% become malignant); mucinous tumors of the ovary; and well-differentiated adenocarcinomas of the uterine cervix, called adenoma malignum [211]. Nine percent of males develop large-cell-calcifying Sertoli cell tumors resembling SCTAT, which have a 10%–20% chance of becoming malignant. Feminization may occur with the benign testicular tumors.

Table 64.5 Cancer risks and screening recommendations for Peutz–Jeghers syndrome

Cancer	Cancer risk (%) to age 64 years	Average age of diagnosis (years)	Age to begin screening (years)	Screening interval (years)	Screening procedures and comments
Colon	39	46	25 or with symptoms	2	Colonoscopy
Stomach	29	30	10	2	EGD
Small bowel	13	42	10 or with symptoms	1	Hemoglobin, small bowel radiography or possibly capsule endoscopy
Pancreas	36	41	30	1–2	Endoscopic ultrasound or Transabdominal ultrasound
Breast	54	37	20 20	2 1	Mammography Self breast examination
Ovarian	21	28	20	1	Pelvic exam and pelvic or transvaginal ultrasound
Uterus	9	37	20	1	Pelvic exam and pelvic, transvaginal, or endometrial ultrasound
Cervix (adenoma malignum)	Unusual	34	20	1	Pap smear
SCTAT	20	40	20	1	Same as uterine and ovarian; almost all women develop SCTAT, but 20% become malignant
Testicular (Sertoli cell tumor)	9 (benign tumor)	9 (benign tumor)	10	1	Physical exam, ultrasound if indicated; 10%–20% of the benign Sertoli cell tumors become malignant
Lung	15	51	–	–	No screening recommendations given

EGD, esophagogastroduodenoscopy (or upper gastrointestinal endoscopy); SCTAT, sex cord tumor with annular tubules.

Genetics and pathophysiology

Peutz–Jeghers syndrome arises from mutations of the *STK11* gene, also called *LKB1*, a tumor suppressor gene on chromosome 19p that encodes a seronine/threonine protein kinase [212]. Possibly up to 96% of PJS families have mutations of *STK11*, when methods to detect large deletions are added to standard mutation detection [214]. A few remaining families do not link to the *STK11* locus, suggesting that other genes may give rise to this condition. Up to 25% of mutations represent de novo mutations [212].

The *STK11* gene affects p53-dependent apoptosis, suppression of cell proliferation, β-catenin phosphorylation (thus the WNT signaling pathway), and cell polarity [215]. Loss of the wild-type allele of *STK11* by mutation, loss of heterozygosity, or promoter hypermethylation has been found in PJS polyps and cancers, verifying the central role of *STK11* as the disease-causing gene of PJS. Genetic testing is commercially available and is performed similar to testing in FAP. A person known to have the clinical syndrome is first tested. If a relevant mutation can be found in the *STK11* gene, other family members can be tested with near 100% accuracy.

Diagnosis, screening, and treatment

Diagnosis is based on the finding of typical melanin pigment spots and characteristic GI polyps. Management involves screening (as outlined in Table 64.5) and removal of all polyps larger than 1 cm in diameter to prevent both benign and malignant complications. Screening guidelines are empirical and based on the risk for GI complications and cancer. Colectomy is sometimes necessary to control colonic polyps and should be considered, especially if neoplastic change is found in the colon. When small bowel polyps become large or symptomatic, surgery is often necessary and includes careful examination of the entire small bowel to eliminate all significant polyps. Intraoperative endoscopy may be a helpful adjunct in this regard, and this is also an appropriate time to examine and remove gastric and duodenal polyps of significant size [216]. The advent of capsule endoscopy and double-balloon enteroscopy may revolutionize the management of PJS [217–219]. Capsule endoscopy may miss polyps but it appears to be more effective than than radiological approaches for small bowel polyp screening [218,220]. Double-balloon enteroscopy has been shown successfully to

remove small bowel polyps in PJS without surgery [219]. Overexpression of COX-2 has been observed in PJS polyps and cancers, and selective suppression of COX-2 has been found to suppress polyposis in PJS [221]. This promising development must await further studies in view of the cardiovascular and cerebrovascular risks identified with COX-2 inhibitory agents [170,171].

Juvenile polyposis syndrome

Epidemiology and clinical characteristics

Juvenile polyposis syndrome (JPS) is an autosomal dominantly inherited condition arising from mutations of the *SMAD4* gene, the *BMPR1A* gene, and rarely of the *ENG* gene. Multiple juvenile polyps are found in the colorectum (98%), stomach (14%), jejunum and ileum (7%), and duodenum (7%) [212,222,223]. There is also a high risk for colon cancer and an increased risk for gastric, duodenal, and pancreatic cancers. The incidence of JPS is about 1 in 100 000 individuals.

The generally accepted clinical criteria for JPS include the following [224]:

- at least five juvenile polyps in the colorectum
- juvenile polyps throughout the GI tract, or
- any number of juvenile polyps in a person with a known family history of juvenile polyps.

Inherited syndromes that exhibit the GI phenotype of JPS must also be ruled out, including Cowden syndrome (CS), Bannayan–Riley–Ruvalcaba (BRR) syndrome, and Gorlin syndrome (see below).

The polyps in JPS vary in size from small sessile nodules to pedunculated lesions measuring 3 cm or larger in diameter. Most large polyps are pedunculated, but small polyps, especially those in the stomach, are sessile. Grossly, most polyps exhibit a surface that is smooth, rounded, reddish-colored, and without fissures or lobulations, except for large polyps, which may appear to be multilobulated. A white exudate is often seen on the polyp surface. On cut section there are cystic spaces filled with mucin. Microscopically, there is abundant lamina propria with benign but often elongated and cystically dilated glands and lack of a smooth muscle core. Excess chronic inflammatory cells are sometimes present. The epithelial lining of the surface and cysts is nondysplastic and reflects the area of the GI tract where the polyp is located [225].

Polyps begin to appear in the first decade of life, and dozens to many hundreds of polyps are present in the fully developed syndrome. Most patients develop symptoms in the first two decades of life. The average age at diagnosis is 18.5 years [226] but may be later [227]. Rectal bleeding with anemia is the most common presenting symptom, followed by abdominal pain, diarrhea, passage of tissue per rectum, and intussusception [212,222]. A rare and often lethal form of the disease can be observed in infancy. It includes large numbers of juvenile polyps, GI bleeding, protein-losing enteropathy, and significant morbidity and even mortality [222]. In some cases JPS is known to co-occur with hereditary hemorrhagic telangiectasia, thus including a risk for aortic aneurysm, pulmonary thrombosis, digital telangiectases, arteriovenous malformations, and digital clubbing [228]. This association is observed only in cases with *SMAD4* causative germ-line mutations. Gastric polyposis is known to occur most commonly with mutations of *SMAD4*, with the phenotype sometimes of massive gastric polyposis [229,230]. Other associated congenital birth defects are found in 15% of cases, most commonly in those with no family history, and include malrotation of the gut, cardiac and cranial abnormalities, cleft palate, polydactyly, and genitourinary defects [222].

The risk of colon cancer is 17%–22% by age 35 years and approaches 68% by age 60 years [212]. The mean age at diagnosis of colon cancer is 34 years, with a range of 15–68 years. The risk of gastric cancer is 21% in those who have gastric polyps [212,224,231]. Pancreatic and periampullary cancers are also reported [222]. The average age at diagnosis of upper GI carcinoma is 58 years, with a range of 21–73 years [232,233]. The cancer risk in JPS is believed to arise from adenomatous tissue within the juvenile polyp, as up to 50% of juvenile polyps in JPS contain areas of adenomatous change. Villous and malignant foci may be seen in larger polyps [234,235]. Cancers of the duodenum, pancreas, and biliary tree have also been reported in JPS [234].

Genetics and pathophysiology

About 15% of clinically defined JPS families are found to have disease-causing mutations of the *SMAD4* gene. Another approximately 25% have mutations in the *BMPR1A* gene, and rare JPS cases have mutations in the *ENG* gene [212,222,236–239]. All three genes are tumor suppressor genes involved in the transforming growth factor-β (TGF-β) signaling family, and directly or indirectly affect cell growth inhibition and apoptosis. Numerous ectopic crypts with frequent intraepithelial neoplasia are observed when bone morphogenetic protein (BMP) signaling is inhibited in the mouse model of JPS [240]. There is some evidence that normal BMP signaling also suppresses WNT signaling to ensure a balanced control of stem cell self-renewal [241]. Biallelic gene inactivation has been noted both in stromal cells and epithelial cells of polyps [222,242,243]. The type of disease mutations usually found in the genes suggests that direct sequence analysis is the most efficient method for mutation detection in this disease [238].

Diagnosis, screening, and treatment

Diagnosis is based on recognition of the disease characteristics and on genetic testing, especially in families. Genetic testing is particularly important in JPS, both to confirm the diagnosis in a proband and to test relatives. Testing is also important to separate JPS from other conditions in which juvenile polyps form, especially Cowden syndrome and Bannayan–Riley–Ruvalcaba syndrome. Genetic testing has also been shown to increase markedly the screening compliance

in relatives of those with JPS [246]. Genetic testing in those with clinical JPS will find a disease-causing mutation in 40%–60% of families. Approximately 25% of newly diagnosed cases are sporadic, that is, represent new or de novo mutations, whereas 75% will have a family history [212].

Colorectal screening should consist of colonoscopy, starting with the onset of symptoms or at age 15 if no symptoms have occurred. It should be repeated every 1–2 years until polyps are clear, and then every 3 years [212,222,244,245]. Upper endoscopy should be performed every 1–2 years beginning at age 25 years or possibly earlier in families with *SMAD4* mutations. The small bowel past the duodenum should be examined if duodenal polyposis is present, or if there is an unexplained anemia or protein-losing enteropathy. Periodic small bowel examination by radiography, push enteroscopy, capsule endoscopy, or even double-balloon enteroscopy may also be appropriate in selected patients. Patients with limited numbers of polyps in any area of the gastrointestinal tract can usually be managed with endoscopic polypectomy.

In JPS patients with large numbers of colonic polyps, anemia or protein-losing enteropathy, polyps with advanced dysplasia, or the presence of invasive adenocarcinoma, subtotal colectomy with ileorectal anastomosis or total restorative proctocolectomy is indicated, depending on the number of rectal polyps [212,222,244]. Subsequent surveillance of the remaining rectum or pouch should be assured [246]. Furthermore, fully half of patients with rectal-preserving surgery require later proctectomy [246]. Complete or partial gastrectomy may also be necessary for patients with advanced dysplasia, gastric cancer, or even massive gastric polypsis that cannot be effectively controlled endoscopically [212,222].

Overexpression of COX-2 has been observed in juvenile polyps of JPS patients, suggesting that selective COX-2 inhibition may be a medical approach to the control of polyposis in this condition [247].

Cowden syndrome

Epidemiology and clinical characteristics

Cowden syndrome (CS), also called *multiple hamartoma syndrome*, is an autosomal dominantly inherited condition characterized by multiple hamartomas of the skin, mucous membranes, GI tract, and other organs, and a high risk for cancer of the breast, thyroid, and perhaps other sites [212,248,249]. This rare disease occurs in about 1 in 200 000 individuals but is believed to be underdiagnosed.

An international consortium has developed diagnostic criteria for CS [249] (Table 64.6). The hallmark of the syndrome is the presence of multiple facial trichilemmomas. Verrucous skin lesions of the face and limbs and cobblestone-like hyperkeratotic papules of the gingiva and buccal mucosa are common. Biopsy examination has demonstrated facial lesions most often to be trichilemmomas, oral mucosal lesions to be fibromas, and all hand and foot lesions to be hyperkeratoses.

Table 64.6 Diagnostic criteria for Cowden syndrome

Pathognomonic criteria
Mucocutaneous lesions:
- Trichilemmomas, facial
- Acral keratoses
- Papillomatous papules
- Mucosal lesions

Major criteria
Breast carcinoma
Thyroid carcinoma (nonmedullary), especially follicular
Macrocephaly (megalencephaly, at least 95th percentile)
Lhermitte–Duclos disease (LDD)
Endometrial carcinoma

Minor criteria
Other thyroid lesions (e.g., adenoma or multinodular goiter)
Gastrointestinal hamartomas
Fibrocystic disease of the breast
Lipomas
Fibromas
Genitourinary tumors (renal cell or endometrial cancer, uterine fibroids) or malformation

Operational diagnosis in a person
1. Mucocutaneous lesions alone if:
   - **a.** There are at least six facial papules, of which at least three must be trichilemmoma, or
   - **b.** Cutaneous facial papules and oral mucosal papillomatosis, or
   - **c.** Oral mucosal papillomatosis and acral keratoses, or
   - **d.** At least six palmoplantar keratoses
2. Two major criteria, but one must include macrocephaly or LDD
3. Two major and three minor criteria
4. Four minor criteria

Operational diagnosis in a family with one member diagnosed with Cowden syndrome
1. One or more of the pathognomonic criteria
2. Any one major criterion with or without minor criteria
3. Two minor criteria

Adapted from Eng [248] and Pilarski and Eng [249].

By the third decade of life, 99% of affected patients have developed mucocutaneous stigmata of the disease [249].

Other common manifestations of the disease include multinodular goiter (50%), follicular (sometimes papillary) thyroid carcinoma (10%), thyroid adenoma, fibrocystic breast disease and breast fibroadenomas (up to 75%), and breast cancer (25%–50%), with a median age at diagnosis of 38–46 years. Gastrointestinal hamartomatous polyps, particularly in the colon, stomach, and duodenum, occur in about 60% of cases. Also observed are multiple early-onset uterine leiomyomas, macrocephaly, and mental retardation. Visceral arteriovenous malformations have also been reported [250]. Other related cancers include those of the endometrium (lifetime risk 5%–

10%), kidney, and possibly colon, ovary, melanoma, lung, and retinal glioma. Male breast cancer has been reported in patients with CS. Additional benign soft-tissue and visceral tumors that have been reported include hemangiomas, lipomas, lymphangiomas, neurofibromas, and meningiomas. Developmental or congenital abnormalities also occur and include hypoplastic mandible, a prominent forehead, and a high-arched palate.

The GI hamartomas occur throughout the GI tract. A review of the reported cases in Japan found polyp distribution among 93 cases to be as follows: esophagus, 66%; stomach, 75%; duodenum, 37%; and colon, 66% [251]. Polyps of the esophagus are actually glycogenic acanthosis, and appear as whitish flat elevations in the esophagus [212]. In the stomach, small bowel, and colon, a number of different types of hamartomas are observed, including juvenile polyps (by far the most common), lipomas, inflammatory polyps, ganglioneuromas, and lymphoid hyperplasia. Juvenile-like polyps that contain some neural elements are considered characteristic of this disease. The GI cancer risk has generally been considered not elevated, although a study from Japan found 9.6% of 93 patients to have colon cancer [251].

Related syndromes

Lhermitte–Duclos disease

The rare occurrence of a benign hamartomatous overgrowth of ganglion cells in the cerebellar cortex (called *dysplastic gangliocytoma of the cerebellum*) is called Lhermitte-Duclos disease (LDD). This same tumor is a known manifestation of CS. It has been found that the large majority of cases of LDD occur as a part of CS. (250, 253, 254).

Bannayan–Riley–Ruvalcaba (BRR) syndrome

This syndrome is characterized by macrocephaly, delayed psychomotor development, lipomatosis, hemangiomatosis, and pigmented macules of the glans penis [212,249,254,255]. Similar to CS, intestinal polyps are primarily juvenile polyps, and some contain ectopic ganglion cells [256]. The majority of BRR syndrome patients mave germ-line mutations of the *PTEN* gene, and an identical mutation can lead to either BRR or CS [249,254,257]. It has been suggested that CS and BRR syndromes be considered together as the *PTEN* hamartoma tumor syndromes.

Genetics

Up to 85%–90% of CS cases and 65% of BRR cases arise from mutations of the *PTEN* gene, when analysis includes large deletions and promoter mutations in addition to standard sequencing analysis [249,258]. The *PTEN* gene encodes a ubiquitously expressed dual-specificity phosphatase, which has tumor suppressor activity. It regulates cellular processes, such as cell cycling, translation, and apoptosis, by blocking activation of AKT, a serine/threonine kinase involved in cell growth and survival [249]. Only 10%–15% of diagnosed cases have an affected parent [212]. There has been a suggestion that typical CS arises more often from 5′ *PTEN* mutations whereas BRR arises more often from 3′ mutations [259].

Surveillance and management

Management of CS involves prevention of the associated cancers. The screening recommendations for CS are given in Table 64.7. Gastrointestinal screening recommendations are given in view of the malignancy risk of other syndromes in which juvenile polyosis is found and because of the survey from Japan that demonstrated an increased risk for colon cancer [251]. It is suggested that individuals with BRR and LDD should have similar surveillance [249,254]. Gastric polyposis has been reported to regress with treatment for *Helicobacter pylori* [260].

Hereditary mixed polyposis syndrome

Three families were described in which the polyposis phenotype links to a locus on chromosome 15, called the

Table 64.7 Cancer risks and screening in Cowden syndrome

Cancer	Cancer risk	Age to begin screening (years)	Screening interval (years)	Screening procedures and comments
Colon	Possibly 9%	15	2	Colonoscopy, intervals may increase or decrease, depending on findings
Upper GI tract and small bowel	Possibly increased	15	2	EGD, examination of the small bowel if duodenal polyposis is present, repeat depending on number of polyps
Thyroid	3%–10%	Adolescence	1	Thyroid exam and baseline ultrasound
Breast	25%–50%	25 30	Monthly 1	Self breast exam Mammography
Uterine	5%–10%	35	1	Blind repel suction biopsies
Renal cell	Possibly increased	18	1	Urine analysis with cytology and possibly renal ultrasound

EGD, esophagogastroduodenoscopy (or upper gastrointestinal endoscopy).
Data from Eng [248], Schreibman et al. [212], and Pilarski and Eng [249].

HMPS gene, which appears to overlap with the colorectal adenoma and carcinoma (*CRAC1*) gene [212]. Affected patients exhibited mixed juvenile–adenomatous polyps and also adenomatous polyps, hyperplastic polyps, serrated adenomas, and mixed hyperplastic–adenomatous polyps and adenocarcinomas, with the polyps occurring in one family at a mean age of 28 years [261].

Gorlin syndrome

Gorlin syndrome, also called *nevoid basal cell carcinoma syndrome*, is an autosomal dominant disorder with an occurrence of 1:55 00 [212,262]. It accounts for about 0.5% of patients with basal cell cancer and occurs secondary to mutations of the *PTCH* gene on chromosome 9q. The primary clinical findings include multiple basal cell carcinomas, mandibular bone cysts, characteristic pits in the skin of the palms and soles, intracranial calcification, large head circumference, and congenital skeletal anomalies. Gastric hamartomatous polyps have been reported as a part of the disease but gastrointestinal findings are often not present.

Polyposis syndromes with neural polyp histology

Neural elements can be observed in the juvenile polyps of CS and BRR, and when found, are somewhat distinctive for those diagnoses. Multiple GI polyps with histological neural elements can also be found in neurofibromatosis type I, in multiple endocrine neoplasia type IIB (MEN IIB), and independently in families without any known syndromes.

Neurofibromatosis type I (NF1)

This disease, also called *von Recklinghausen disease*, is defined by the presence of more than five cutaneous café-au-lait spots together with frequent neurofibromas of the skin [262]. The incidence is 1 in 3000, and one-third to one-half of cases are new mutations. The condition is autosomal dominantly inherited and arises from mutations of the tumor suppressor gene *NF1*, on chromosome 17q. The *NF1* gene encodes neurofibromin, which is a negative regulator of RAS signaling [263,264]. About 25% of affected patients exhibit multiple intestinal polypoid neurofibromas and, less commonly, ganglioneuromas [265,266]. The small bowel is affected most commonly, followed by the stomach and then the colon. Gastrointestinal symptoms are unusual but may include GI bleeding, intussusception, or obstruction [267,268]. Neurofibrosarcoma has only rarely been reported.

In addition to neuromas, other GI tumors associated with NF1 include ampullary carcinoid, pheochromocytoma, and gastrointestinal stromal tumors (GISTs) [264]. In fact it has been suggested that GISTs are the most common NF1-associated GI tumors. Furthermore, most GI tract mesenchymal tumors previously interpreted as other tumor types probably represent GISTs [264]. In NF1 GISTs are most commonly found in the jejunum and ileum, followed by the duodenum and then stomach. Malignant behavior of the GISTs is associated with tumors measuring more than 5 cm or having a high mitotic rate, but not with multiple small tumors. The most common presenting symptoms were intermittent gastrointestinal bleeding and anemia. Amost none of the GIST tumors in NF1 demonstrates *KIT* or *PDGFRA* mutations, which are usually observed in sporadic GISTs. Instead, somatic inactivation of the wild-type *NF1* allele appears to be the pathogenetic basis of GISTs in NF1 [263].

A syndrome of early-onset colon cancer, hematological malignancies, and features of NF1 is known to occur with inherited homozygous mutations of mismatch repair genes associated with HNPCC [269,270]. There is evidence that the *NF1* gene is a mutational target in mismatch repair dysfunction [270].

Multiple endocrine neoplasia type IIB (MEN IIB)

Also known as the *mucosal neuroma syndrome*, MEN IIB is characterized by the presence of multiple tumors, including medullary thyroid carcinoma at a young age (almost all patients), pheochromocytoma (40%–50%), enlarged and nodular lips (from ganglioneuromas), a marfanoid habitus, and ganglioneuromatosis of the GI tract (40%) [212,271]. Ganglioneuromatous polyps occur throughout the GI tract, from lip to anus, but most commonly in the colon and rectum [272]. Gastrointestinal symptoms, including diarrhea and constipation, are common (more than 90% of cases) and arise from dysmotility of the GI tract secondary to the underlying often transmural ganglioneuromatoses [212]. Symptoms often begin in the first months of life and may present as megacolon. A single mutation at codon 918 in the tyrosine kinase domain of the RET receptor (encoded by the *RET* protooncogene on chromosome 10q) is found in up to 95% of cases [212]. About half of cases are considered to represent new mutations.

Isolated intestinal neurofibromatosis of the colon

Multiple colonic ganglioneuromas have been observed in families and isolated cases unrelated to NF1 or MEN IIB [273]. The observed ganglioneuromas are both microscopic and polypoid. There may be dozens of visible colonic polyps ranging up to 0.5 cm in diameter. The distribution of affected individuals in the one family described was typical of autosomal dominant inheritance.

Polyposis syndromes of uncertain etiology

Cronkhite–Canada syndrome

Cronkhite–Canada syndrome (CCS) is an acquired condition characterized by generalized GI polyposis, cutaneous hyperpigmentation, hair loss, and nail atrophy [274–276].

The syndrome has a worldwide distribution. Sixty percent of reported cases occur in men, and the average age at symptom onset is 59 years, with a range of 31–86 years. No familial occurrences have been observed. Nutritional, infectious, and immunological associations have been discussed, but the cause of CCS remains elusive.

The polyposis of CCS is present throughout the GI tract except for the esophagus [276]. Hundreds of polyps are observed, with polyp size ranging from a few millimeters to 3 cm in diameter. Colonic polyps are almost always sessile, even when large, which can often differentiate them from juvenile polyps. Ulceration and friability are surface features of some of the polyps. Microscopically, the polyps are almost identical to juvenile polyps. In contrast to JPS, however, the mucosa between polyps is also histologically abnormal, with edema, congestion, and inflammation of the lamina propria and focal glandular ectasia. Polyps may appear over several years or several months. They usually resolve after remission of symptoms, but they may persist for years. Adenomatous change and colon cancer have been reported in the hamartomatous polyps of this syndrome [274]. The overall incidence of colon cancer appears to be about 12%–15% [277]. Carcinoma of the stomach is also reported as a consequence of CCS.

A number of extraintestinal, ectodermal manifestations are observed in almost all patients with CCS. Nails of the fingers and toes exhibit various degrees of dystrophy, described as thinning, splitting, and partial separation from the nail bed (i.e., onycholysis). Hair loss occurs over a few weeks on the scalp, eyebrows, face, axillae, pubic area, and extremities. Hyperpigmentation is described as dark, brownish macules, ranging from a few millimeters to 10 cm in diameter, and it occurs over the upper extremities, followed by the lower extremities, face, palms, soles, neck, back, chest, and scalp, in that order. The nail, hair, and pigmentation abnormalities are all reversible on remission of the disease.

Hypogeusia is the dominant initial symptom in most patients, which is soon followed by diarrhea, abdominal discomfort, anorexia, and weight loss [277]. Variable degrees of fat, protein, and disaccharide malabsorption occur because of a decreased absorptive surface. Other common symptoms include fatigue, weakness, edema, nausea, and vomiting.

The disease often exhibits a fairly acute onset and a rapidly progressive course. Weight loss and edema ensue, and ectodermal changes occur in a few weeks to a few months. Gastrointestinal bleeding also may occur and can be severe in some cases. Intussusception from small bowel polyps has been reported but is unusual. The diarrhea and protein-losing enteropathy may be extremely severe, resulting in profound malnutrition. Complications resulting from malnutrition are a major cause of morbidity and mortality in this syndrome. They include severe cachexia, anemia, congestive heart failure, and impaired immunity, resulting variously in pneumonia, sepsis, and septic shock. The disease may be fatal within a few months, although a more protracted course is also possible, especially if the patient responds to therapy or remits spontaneously.

A number of spontaneous remissions have been reported in CCS, and partial or complete remissions have resulted from several different interventions [275]. Therapies have included corticosteroids, antibiotics, colectomy, parenteral nutrition, and combinations of these, each with variable success. Recommendations are for aggressive supportive therapy, including enteral or intravenous alimentation. Corticosteroid therapy is undertaken if deterioration continues, and antibiotic therapy may be attempted, although its usefulness is questionable. Surgery is most often used to treat complications, including bleeding, malignancy, intussusception, and sometimes protein-losing enteropathy. Colonoscopy should be performed, if feasible, to consider the possibility of malignancy. Periodic examination of the colon and stomach seems to be indicated in long-term survivors with persistent polyps to screen for adenomatous change and colon cancer.

Hyperplastic polyposis syndrome (HP)

Rare patients are described with large numbers of hyperplastic polyps distributed throughout the colon [278–281]. In such patients, polyps are most often sessile, 1–7 mm in diameter, but larger, sessile or pedunculated hyperplastic polyps may also be observed. Smaller polyps are distributed equally throughout the colon, whereas larger lesions often have a proximal colonic distribution [279]. Some adenomas and serrated adenomas are observed in the majority of hyperplastic polyposis cases. Colon cancer has often been reported with HP although its exact risk is unknown [279–281]. Familial cases have been reported, albeit rarely. Germ-line mutations for HP have not been identified, but chromosome 1p allelic loss has been observed in large polyps of HP patients [282].

Working criteria have been suggested to assist with the diagnosis of HP:

- at least five hyperplastic polyps proximal to the sigmoid colon with two or more of them larger than 10 mm in diameter
- any number of hyperplastic polyps proximal to the sigmoid colon in an individual who has a first-degree relative with HP, or
- more than 30 hyperplastic polyps of any size, but distributed throughout the colon [278].

As adenomas are present in the majority of cases and some cancer risk is likely, surveillance of patients with HP is indicated. Management includes colonoscopic polyp removal, every 1–3 years, depending on the number and size of hyperplastic and adenomatous polyps. Subtotal colectomy should be considered if polyposis cannot be controlled endoscopically or if there is a diagnosis of histologically advanced polyps or colon cancer.

Polyposis syndromes with inflammatory polyps

Inflammatory bowel disease

Multiple inflammatory polyps are frequently found in both ulcerative colitis and Crohn's disease. The polyps represent remaining normal tissue, with inflammatory elements that persist during the healing phases of the diseases. The polyps themselves have no malignant potential, although both ulcerative colitis and Crohn's disease have a colon malignancy risk that parallels the extent of colonic involvement and the duration of the disease.

Devon polyposis

Devon polyposis, also known as *Devon family syndrome*, was described in a family in which three generations of females were found to have multiple inflammatory fibroid polyps of the ileum [283]. The polyps varied in size from 0.5 to 8 cm, and each affected person experienced intussusception or small bowel obstruction. Similar polyps were found in the gastric antrum of one patient. Histologically, the polyps were benign proliferations of histiocytes.

Cap polyposis

Cap polyposis is a rare syndrome of multiple inflammatory polyps in the rectosigmoid, although it may occasionally be observed higher in the colon and even in the stomach [284,285]. Histologically, the polyps are inflammatory, with elongated tortuous crypts covered by a "cap" of granulation tissue. There is also smooth muscle and elastin in the mucosa, suggesting that cap polyposis, together with solitary rectal ulcer syndrome, inflammatory cloacogenic polyps, and gastric antral vascular ectasia, is part of a group of conditions referred to as "mucosal prolapse syndrome" [284,286]. Indeed, in solitary rectal ulcer syndrome, multiple 1–3-mm polypoid lesions in the distal rectum can also be observed.

Clinically, patients may have diarrhea, rectal bleeding, and protein-losing enteropathy [286]. A history of straining at stool is often elicited [284]. Endoscopically there may be from 1 to over 100 polyps, which are small, red, sessile, and covered with a layer of fibrinopurulent exudates or with an eroded surface [284,285]. Medical treatment, with variable success, has included metronidazole, immunosuppressive agents, and avoidance of intralumenal trauma [284,287]. Once case of cap polyposis of the stomach and colon responded to eradication of *H. pylori* [288], whereas another colonic case responded completely to infliximab therapy [289]. Solitary polyps can be removed endoscopically, whereas patients with multiple polyps may require surgical resection of the involved colonic segment if medical therapies are unsuccessful [284].

Polyposis conditions arising from lymphoid tissue

Nodular lymphoid hyperplasia

Nodular lymphoid hyperplasia (NLH) is a rare polyclonal lymphoproliferative disorder of unknown cause that, in most cases, is not related to a distinct disease [290]. It is found in the terminal ileum of some patients with Gardner syndrome, in about 20% of patients with common variable immunodeficiency syndrome, as a rare association with intestinal lymphoma [291], and in some otherwise healthy children and some adults [292,293]. It has been suggested that hyperplasia of the lymphoid nodules occurs as a local immune response to antigens in the gut lumen. It has also been suggested that cellular immune dysfunction, as well as immunoglobulin deficiency, must be present for NLH to be present [294].

The hyperplastic lymphoid nodules of NLH are most often found in the small bowel but may also occur in the stomach and colon. They are described as numerous, 3–6 mm in diameter, and exhibiting the same color as surrounding mucosa. Occasionally, nodules may reach 10 mm or more in diameter. The enlarged lymphoid follicles are morphologically indistinguishable from lymphoid follicles that occur normally in the GI tract. The nodules themselves do not usually cause symptoms, which are more likely related to the underlying conditions.

The primary clinical issue is to distinguish NLH from normal lymphoid tissue, follicles of which range from 0.6 to 3 mm in diameter and occur throughout the gut [295]. Barium enema may reveal lymphoid follicles without evidence of disease in up to 50% of individuals younger than 30 years of age and in up to 17% of those older. Normal lymphoid tissue is also frequently observed endoscopically, especially with melanosis [296]. Lymphoid hyperplasia of the terminal ileum is found in almost half of patients examined by colonoscopy [297]. Follicles range in size from 1 to 10 mm or more, and are larger, more numerous, and more frequent in younger individuals. Immunohistochemical staining and tissue genotyping can be used to distinguish malignant changes of lymphoid tissue and NLH [298]. No therapy is merited for NLH per se.

Multiple lymphomatous polyposis

About 30% of primary extranodal lymphomas occur in the GI tract. Most of these present as a single lesion, although about 10% exhibit GI polyposis, including multiple lymphomatous polyposis (MLP) and immunoproliferative small intestinal disease (see below) [299,300].

Multiple lymphomatous polyposis is a rare intestinal malignancy characterized by the presence of numerous GI polypoid lesions of malignant lymphoma. A non-Hodgkin B-cell lymphoma that is the GI counterpart of mantle cell

lymphoma [301,302], MLP arises from a malignant transformation of lymphocytes that exhibit homing receptors for lymphoid tissue of the GI tract, thus giving rise to a diffuse polyposis presentation [303]. The polyps measure from a few millimeters to several centimeters, involve the small and large bowel in 80%–90% of cases, and the stomach or duodenum in 50% of cases [304]. This condition occurs predominantly in men (88%), with reported cases ranging in age from 43 to 82 years at the time of diagnosis [305]. Symptoms are nonspecific, including weight loss, fatigue, diarrhea, abdominal pain, anemia, and occult GI bleeding. The condition often exhibits extraabdominal dissemination, especially to peripheral lymph nodes. Chemotherapy is the treatment of choice, although the overall prognosis is poor [306].

Mucosa-associated lymphoid tissue (MALT) lymphomas, follicular lymphomas, and primary T-cell lymphomas have also been described that are morphologically similar to MLP in that they exhibit a multiple polypoid appearance in the GI tract and are thus considered types of MLP [301,307–312].

Immunoproliferative small intestinal disease

Immunoproliferative small intestinal disease (IPSID), previously called both *Mediterranean-type lymphoma* and *α-heavy chain disease*, can also exhibit multiple nodular lesions of the small bowel [312]. It is a MALT lymphoma characterized by infiltration of the bowel wall with a plasma-cell population that secretes a monotypic truncated immunoglobulin α heavy chain lacking an associated light chain [313,314]. Evidence indicates that most cases arise as a result of infection with *Campylobacter jejuni* [314]. Those most commonly affected by IPSID are people in their second or third decade of life living in the Mediterranean region. Patients present with a malabsorption syndrome lasting months to years that includes chronic diarrhea, weight loss, and abdominal pain. Small intestinal endoscopy may variously show thickened mucosal folds, diffuse nodularity, ulcers, a mosaic pattern, and nondistensibility from infiltration.

Histologically, IPSID begins as an intense proliferation of plasma cells in the lamina propria. It eventually proceeds to an overt malignant lymphoma with extension beyond the lamina propria and sometimes the occurrence of multiple nodular lesions. The process may remain in deeper intestinal layers, however, requiring full-thickness biopsy for diagnosis. An abnormal paraprotein is frequently present, which represents the α-chain fragment of immunoglobulin A. Unlike MLP, IPSID is confined to the gut and is most often present in the small bowel, particularly the proximal small bowel.

Early-stage IPSID responds to antibiotics, resulting in a 30%–70% rate of complete remission [313]. Treatment has included tetracycline or metronidazole and ampicillin or tetracycline. Early-stage patients who do not respond to antibiotic therapy after 6 months should then receive combination chemotherapy. Antibiotics and chemotherapy should be given together for more advanced cases. Most untreated IPSID patients progress to lymphoplasmacytic and immunoblastic lymphoma invading the intestinal wall and mesenteric lymph nodes, and also possibly invading distant organs. This type of lymphoma shares clinical, morphological, and molecular features with MALT lymphoma, lymphoplasmacytic lymphoma, and plasma cell neoploasms [313]. Although unusual, the treatability of this condition in its early stages, but the poor outcome in later stages, require that gastroenterologists be familiar with this condition as a cause of proximal small bowel nodularity.

Miscellaneous noninherited polyposis syndromes

There have been a number of reports of leiomyomatosis of the colon and other segments of the GI tract [315–317]. A multinodular submucosal tumor appearance is observed lumenally, which reflects single or multiple benign growths of smooth muscle of the bowel wall.

Lipomatous polyposis is also rarely observed [318]. In one case, between 700 and 1000 lipomatous polyps were observed, but about 60 adenomatous polyps were also present. Polyps were 2–50 mm in diameter, were found throughout the colon, but were more dense in the left colon [318]. In another case, dense colonic lipomatous polyposis was observed together with lipomas of the peritoneum [319]. A third patient was found to have multiple lipomas throughout both the small and large intestine and a presentation of intussusception [320].

Lymphangiomas are unusual solitary lesions in the colon, representing dilation or overgrowth of lymphatic channels. Clusters of elevated but apparent submucosal colonic polypoid lesions were observed colonoscopically in a case in which the lesions were found to be multiple lymphangiomas [321].

Finally, pneumatosis cystoides intestinalis, which is characterized by multiple air-filled cysts of the GI tract wall, can have the appearance of polyposis on barium enema and colonoscopy [322]. The diagnosis is made by abdominal radiography or colonoscopic biopsy.

Colorectal adenocarcinoma is a major human health problem. Worldwide this malignancy affects 1 million individuals each year and causes 500 000 deaths annually. Although colorectal cancer occurs mainly in Western and industrialized countries, since 1950 the incidence of this neoplasm has also increased in traditionally low-incidence regions. In United States, each citizen has a 6% lifetime risk of colorectal cancer, and, strikingly, this tumor is the second leading cause of cancer-related death after lung cancer. In 2005, 145 000 persons were diagnosed with and 56 000 individuals died of colorectal cancer in the United States.

Since the early 1990s a significant basic science and clinical research effort has focused on colorectal cancer. This investigation has resulted in a series of seminal discoveries, both generally in the understanding of tumor biology and specifically in the pathogenesis of colorectal cancer. In some individuals with this malignancy, germ-line mutations are the readily identifiable cause. But in most, the development of cancer appears to be a complex interaction between the host genome and environmental factors.

Advances in knowledge of colorectal cancer have resulted in improvements in surgical/endoscopic techniques, epidemiology, screening, and surveillance of high-risk groups. Moreover, in the past decade, several new chemotherapeutic agents have been developed as a result of our basic scientific understanding of tumor biology. Yet, despite these advances, surgery still remains the treatment offering the greatest hope for cure. Because colorectal cancer usually arises over a prolonged period and is accessible to screening techniques, secondary prevention remains the best way to decrease death from this malignancy.

This chapter provides an up-to-date description of the state of knowledge regarding the epidemiology, etiology, pathogenesis, clinical features, pathology, and treatment of colorectal cancer.

Epidemiology

Statistics: incidence and mortality

Colorectal cancer is an important global health problem. In 2000, an estimated 944 717 incident cases of colorectal cancer were diagnosed worldwide, with almost equal gender distribution: 498 754 cases in males and 445 963 in females [1]. Globally, about 500 000 individuals die annually from this malignancy [2]. Worldwide, colorectal cancer is the third most commonly diagnosed malignancy after lung and breast cancer [3].

The United States is a high-risk country for colorectal malignancy (Fig. 65.1). Statistics from 2005 estimate 145 290 incident cases of colorectal cancer annually, of which 40 340 are rectal malignancies [4]. Colorectal cancer accounts for about 56 290 deaths per year, or roughly 10% of all US cancer-related mortality annually, and ranks as the second leading cause of cancer death after lung cancer. The lifetime risk for colorectal cancer in the United States is 6% for both genders, and the lifetime risk of death from this tumor is 2.6% in men and 2.7% in females [3]. In unscreened individuals over 50 years of age, prevalence studies estimate one or more neoplastic lesions in 37.5% of individuals, an adenoma of 1.0 cm or greater in 7.9%, an adenoma with high-grade dysplasia in 1.6%, and invasive cancer in 1.0% [5].

The incidence of colorectal cancer is influenced more heavily by age than any other demographic variable. Sporadic colorectal cancer is rarely diagnosed before the age of 40. The incidence of this malignancy increases dramatically between 45 and 50 years of age, with 90% of cases occurring after the age of 50 years [6,7]. Consequently, deaths from colorectal cancer begin to increase slowly in the fifth decade of life, rising steeply with advancing age [6,7].

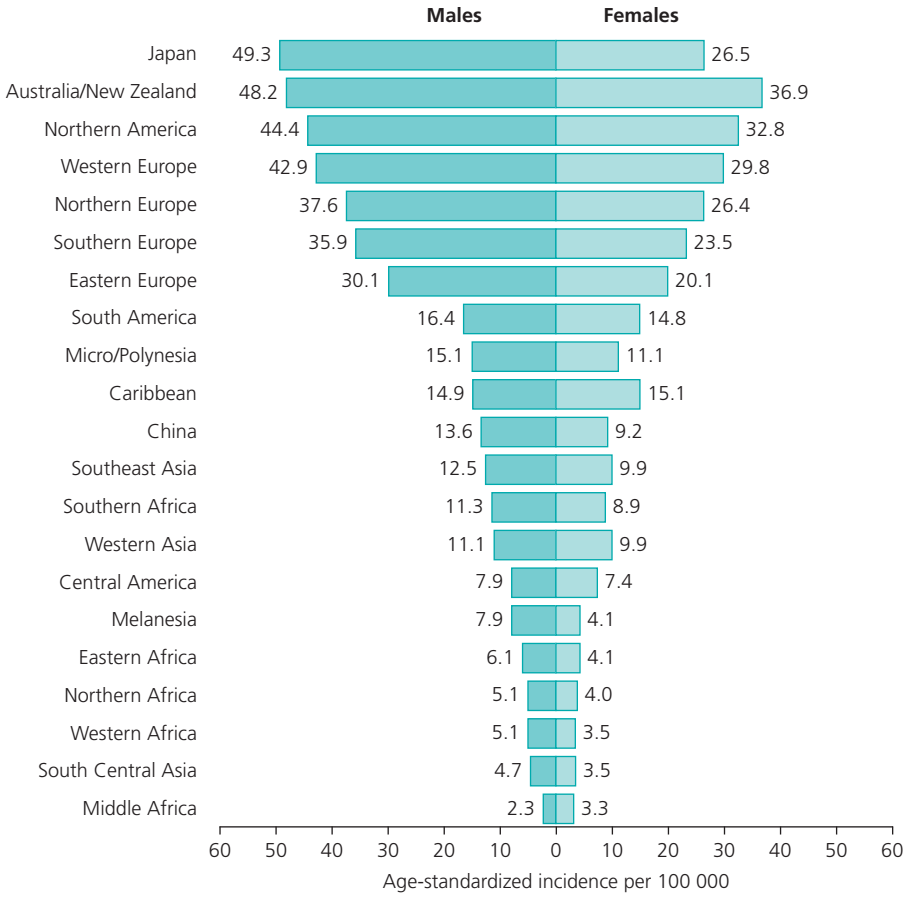

Figure 65.1 Age-standardized incidence rates for colorectal cancer. Data are shown per 100 000 by gender. From Parkin et al. [3], with permission from Lippincott, Williams and Wilkins.

Trends

In general, the incidence of colorectal cancer continues to increase rapidly in countries with formerly a low risk (particularly Japan but also Asian countries). In high-risk countries, the trends are either gradually increasing or stabilizing (north and west Europe) or declining with time (North America) [3]. In the United States (as noted by the annual age-adjusted rate calculated for the past 30 years) the high point of colorectal cancer incidence for both genders occurred the mid-1980s. Since then, the rate has steadily declined, with colorectal cancer incidence decreasing 20% from 1985 to 1995. In 2001 the annual age-adjusted incidence rates of colorectal cancer for men and women were approximately 44.4 and 32.8 cases per 100 000 population, respectively [4]. In the United States, death rates from colorectal cancer have been declining in men since the early 1980s and in women since the late 1940s [4]. From 1985 to 1995 mortality from colorectal cancer decreased by 23%. In 2001, the annual age-adjusted colorectal cancer death rate for men and women was approximately 25 and 22 per 100 000 population, respectively.

Geographical variation

The occurrence of colorectal cancer varies greatly worldwide, with an almost 25-fold difference between specific populations in high- and low-risk regions (Fig. 65.1) [3]. The highest annual incidence rates occur in Australia and New Zealand, followed by North America and Japan (75.8 to 85.1 per 100 000). Incidence tends to be lowest in middle, south central, and western Africa (5.8 to 8.6 per 100 000). The geographical distribution of colon and rectal cancer is similar although the variation between countries is more striking for colon cancer. In high-risk countries like the United States, the ratio of colon to rectal cancer is about 2:1, and in low-risk areas it is closer to 1:1 [3]. This marked variation in geographical incidence for colorectal cancer is largely ascribed to differences in environmental factors, including diet (ingestion of meat, animal fat, and fiber), physical activity, and body weight.

Geographical differences also occur within the United States. For example, the annual age-adjusted morality rates for white males vary three- to four-fold according to region [8]. Mortality rates for colon cancer are the highest in the northeast quadrant of the United States, which includes New England, mid-Atlantic and Midwestern states. In contrast, rates across the South and West have continued to remain relatively low. Similarly, for rectal cancer higher rates are noted in the northeastern, mid-Atlantic, and Midwestern areas, with low rates in the southern United States. Explanations for increased rates of colorectal cancer in the northeastern US

have focused on increased risks for urban populations with a high socioeconomic level [9], but dietary and nutritional factors are likely involved [10–12].

Race/ethnicity

In the United States, African Americans have the highest incidence of colorectal cancer of any racial or ethnic group [13,14]. Since 1985, incidence rates of colorectal cancer have decreased for whites of both genders but, by contrast, have increased for African American men and stabilized for African American women. From 1996 to 2000, incidence rates in African American men were 12.3% higher than in white men and 17.5% higher in African American women than in white women [14].

Also, the mortality rates by gender in African Americans are higher than in whites [8]. Moreover, from 1992 to 1999, the 5-year survival rate from colorectal cancer was 53% in African Americans and 63% in white Americans [14]. This difference in survival also persists when adjusted for stage of colorectal cancer [15]. The cause of the higher incidence of colorectal cancer in African Americans is unknown, but numerous environmental factors have been cited, including increased smoking rates, diet, and physical inactivity, as well as variability in screening frequency and lower use of diagnostic testing [16–19]. The poorer survival in African Americans has been ascribed to lower screening rates, less use of diagnostic tests, and more restricted access to health care [17,18,20].

Ethnic differences can also account for inherited predilection to colorectal cancer. An example is the inherited I1307K mutation of the adenomatous polyposis coli (*APC*) gene, which is noted in approximately 6% of the Ashkenazi Jewish population and less frequently in Sephardic Jews but not found in non-Jewish Caucasian or African American populations [21,22]. This germ-line mutation roughly doubles the lifetime risk of colorectal cancer.

Migration studies

Underscoring the role of environmental factors in the pathogenesis of colorectal cancer are studies of migrating populations. In essence, immigrants adopt the incidence of colorectal cancer in their new homeland. The classic study of this phenomenon documented progressively increasing rates of colorectal cancer in Japanese immigrants to Hawaii and then to the continental United States [23]. Additional examples are the higher subsequent rates in persons moving from China to the United States [24], and from Europe to Australia after World War II [25]. Conversely, people from Scotland, a relatively high-risk area, show a reduction in risk after emigrating to Australia, a relatively low-risk area [25]. These studies highlight the potential for large benefit through primary prevention of colorectal cancer by alteration of diet and lifestyle.

Anatomical trends

Analysis of US colorectal cancer incidence data reveals that about 40% of malignancies occur in the right colon (cecum, ascending colon, hepatic flexure, and transverse colon), 31% in the left colon (splenic flexure, descending colon, and sigmoid colon), and 29% in the rectum (Fig. 65.2) [26]. Several investigators have reported a shift in the incidence of cancer from the left to right colon since the early 1980s [27–30]. Previously, equal proportions of cancers were found in the three anatomical locations noted above [26]. The proximal migration of colorectal cancer over time is probably not attributable to a true increase in the incidence of right-sided colorectal cancer but to a decrease in the incidence of distal colorectal cancer and aging of the population with older persons having more right-sided tumors [26].

Socioeconomic cost

An analysis of the economic burden of colorectal cancer treatment in the United States estimated the cost at $6.5 billion per year, or 12% of the $40 billion annually spent on cancer care [31]. This figure is second only to breast cancer and greater than the cost of lung or prostate cancers. Examination of US hospital discharge data in the 1990s revealed the average number of hospital admissions for colorectal cancer was 237 000 per year, with total mean hospital charges of $4.6 billion dollars annually [32]. Based on census projections, the annual number of colon cancer admissions is estimated to increase 70% in the next 40 years [32]. Dramatic future increases in the cost of treatment of colorectal cancer are foreseen with the advent of monoclonal antibody chemotherapy, which quintuples therapeutic costs [33]. Evidence suggests that the attributable cost of care for colorectal cancer can be significantly reduced by screening the population at age 50, because most hospital admissions involve those aged over 60 years [34].

Etiology

In a minority of cases, the occurrence of colorectal adenocarcinoma is directly attributable to a definable, usually inherited, molecular cause. However, in the vast majority of patients, this tumor results from a complex interaction between environmental factors and genetic predisposition. The role of environmental determinants, especially diet, is strongly highlighted by studies of colorectal cancer incidence in migrant populations, as noted above. Moreover, an analysis of a cohort of US men concluded that six modifiable factors (body mass index, physical activity, alcohol consumption, folic acid supplementation, smoking, and red meat ingestion) resulted in a population attributable risk for colorectal cancer of 71%, suggesting that most of colon cancer in this group

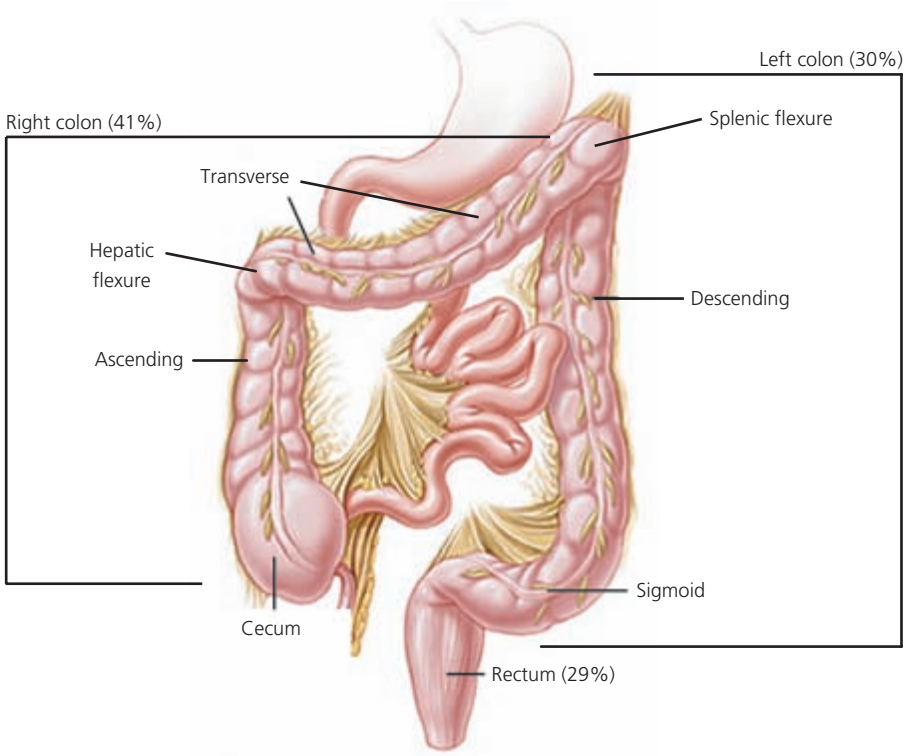

Figure 65.2 Location of colorectal cancer in the large intestine. Adapted from Johns Hopkins Gastroenterology and Hepatology Resource Center (http://hopkinsgi.org), with permission.

Table 65.1 Environmental risk factors in the causation of colorectal cancer

Risk factors	Increased risk (RR[a])
High red meat intake	1.5–3.6
Obesity	2.0
Cigarette smoking	1.9
High calorie intake	1.7
Alcohol intake	1.4–1.7
High fat intake	1.2
Protective factors	**Decreased risk (RR[a])**
Physical activity	0.70–0.80
High calcium intake	0.54–0.85
Folate intake	0.25–0.66
Selenium intake	0.58
Estrogen/progesterone hormone treatment	0.63–0.82
Nonsteroidal antiinflammatory drugs	0.58–0.60
Dietary fiber intake	0.58–0.65
Vegetable and fruit intake	0.48

a RR, relative risk estimates.

was potentially avoidable [35]. In the following section, the environmental (Table 65.1), genetic (Table 65.2), and other factors (Table 65.3) that appear to influence the risk of human colorectal cancer are described.

Environmental factors

Energy balance, obesity, and body habitus

Literature from animal studies suggests that the most powerful and consistent dietary influence on carcinogenesis is energy intake [36]. Indeed, cohort and case–control human studies note a relationship between high levels of energy intake and increased risk of colorectal cancer (odds ratio [OR] 1.70) [37,38]. In one analysis, the risk of colorectal cancer increased 2.3% per 100 calories per day [38].

The study of energy intake in humans is complex and often inaccurate. Nevertheless, indirect indicators of energy balance, such as bodyweight, also support this relationship. A positive association between adiposity and risk of colorectal neoplasia (adenoma and cancer) is noted in numerous case–control and prospective cohort studies [39–48]. Overall a modest two-fold increased risk of colorectal neoplasia is seen with a body mass index greater than 30 [46]. Also, body fat distribution may be an important factor. Case–control studies generally reveal that higher waist-to-hip ratios (central obesity) are associated with increased prevalence of colorectal adenomas and carcinomas [39,42,45–47].

Meat

Concepts about the role of meat, specifically red meat, have been constantly evolving. In the past, consumption of animal meat has been linked to colorectal cancer. This notion is supported by several key studies. The Nurses' Health Study reported that comparison of women who consumed red

Table 65.2 Hereditary factors that cause colorectal cancer

Syndrome	Genotype	Inheritance	Phenotype	Colorectal cancer risk (%)
Familial adenomatous polyposis (FAP)	*APC* gene mutation	AD	≥ 100 colorectal adenomas	~ 100
Attenuated FAP (AFAP)	*APC* gene mutation	AD	< 100 colorectal adenomas	~ 100
Crails syndrome	*APC* gene mutation	AD	Polyposis and medulloblastoma	~ 100
MYH-associated polyposis (MAP)	*MYH* biallelic mutation	AR	< or ≥ 100 colorectal adenomas	?
MYH colorectal cancer	*MYH* monoallelic mutation	AD	Colorectal cancer	~ 9
Hereditary nonpolyposis colorectal cancer (HNPCC)	MMR gene mutation	AD	Colorectal cancer and extracolonic cancers	~ 80
Turcot syndrome	MMR gene mutation	AD	HNPCC and glioblastoma	~ 80
Muir–Torre syndrome	MMR gene mutation	AD	HNPCC and sebaceous neoplasms	~ 80
Trimbath syndrome	MMR biallelic mutation	AD	Early-onset HNPCC, oligopolyposis lymphoma, café-au-lait spots, glioblastoma	> 80
Attenuated HNPCC	*MSH6* gene mutation	AD	Less colorectal cancer, increased uterine cancer	30–69
Peutz–Jeghers syndrome	*STK11* (*LKB1*) mutation	AD	Peutz–Jeghers polyps predominantly small intestine	~ 39
Juvenile polyposis	*SMAD4* and *BRPR1A* mutations	AD	Juvenile polyps predominantly colon	17–63
Cowden syndrome	*PTEN* mutations	AD	Hamartomatous polyps GI tract	~ 9
Bannayan–Riley–Ruvalcaba syndrome	*PTEN* mutation	AD	Hamartomatous polyps GI tract	~ 9
I1307K *APC* gene mutation	*APC* gene mutation in codon 1307	AD	Colorectal cancer	~ 20
Family history of adenoma/carcinoma	?	?	Colorectal cancer	11–26
Mixed polyposis	CRCA1	?	Colorectal neoplasia	?

AD, autosomal dominant; AR, autosomal recessive; GI, gastrointestinal; MMR, mismatch repair.

meat frequently with those who consumed red meat rarely showed a statistically significant 2.5-fold increase in risk of colorectal cancer for the former [49]. Data from a cohort study of over 47 000 US male health professionals revealed that men consuming five or more servings per week of beef, pork, or lamb had a relative risk of colorectal cancer of 3.57 compared with those eating these foods less than once a month [50]. Other studies raise concerns about the processing and cooking of meat, particularly the oncogenic nature of heterocyclic amines produced when meat is heated. One report noted an OR for colon cancer of 2.7 (6.0 for rectal cancer) for the most frequent consumers of fried meat with a heavily browned surface, and a 3.5-fold increase in risk for those preferring well-done meat [51].

When long-term risk of meat consumption was evaluated in a cohort of over 148 000 adults, persons in the highest tertile of consumption had a higher risk of distal colon cancer associated with processed meat (relative risk [RR] 1.50), and the ratio of red meat to poultry and fish was 1.53 relative to the consumption pattern of those persons in the lowest tertile. Also, long-term consumption of poultry and fish was inversely associated with risk of both proximal and distal colon cancer [52]. Moreover, in a metaanalysis of cohort studies, an overall positive association was seen, which was strongest for processed meats [53]. By contrast, five groups of vegetarians, totaling 76 000 individuals, originating from three different countries with socially matched controls were analyzed. Mortality from colorectal cancer was not distinguishable between vegetarians and controls (nonvegetarians) [54].

At present, it appears that increased risk exists from red meat ingestion, possibly from meat cooked at high temperatures [55]. Potential mechanisms for this risk include heterocyclic amines formed in cooking, nitroso compounds in processed meats, or ingestion of heme iron [56].

Fat

A moderately strong association between dietary fat and colorectal cancer risk is suggested by animal and epidemiological

Table 65.3 Other factors in causation of or association with colorectal cancer

Factor	Increased risk (RR[a])
Ureterosigmoidostomy	> 4.0
Previous colorectal cancer	> 3.0
Inflammatory bowel disease	> 3.0
Uterine cancer – early onset[b]	> 3.0
Ovarian cancer – early onset[b]	> 3.0
Acromegaly	2.1–4.9
Streptococcus bovis infection	3.0
Dermatomyositis	2.5
Radiation to prostate[c]	1.7
Diabetes mellitus	1.4
Cholecystectomy	1.2

a RR, relative risk estimates compared with general population.
b Early onset before 50 years of age.
c Risk is for rectal not colon cancer.

data. In animal models of colorectal cancer, high-fat diets are associated with increased cancer development [57]. Older epidemiological data note a good correlation between national consumption of fat (grams of fat per person per day per country) and national age-adjusted mortality from colorectal cancer. Countries with a high fat consumption have six times the quantity of fat ingestion and roughly six times the age-adjusted death rate compared with the lowest fat-ingestion nations [58]. Further epidemiological studies examining the association between self-reported dietary fat intake and colorectal cancer risk note that high levels of dietary fat, particularly animal fat, are usually associated with an increase in colorectal cancer [59]. Also, evidence for a stronger risk with saturated and animal fat compared with total fat exists, but the data are not convincing [60]. Not all studies support the role of fat in the genesis of colorectal cancer. A combined analysis of 13 case–control studies involving 5287 cases and 10 478 controls from various populations failed to show any increased risk with any dietary fat variable after adjustment for total energy intake [61]. However, a review of 19 case–control and cohort studies that analyzed colorectal cancer or adenoma risk and dietary intake revealed that over half showed positive correlation, with a relative risk of over 1.2 in patients with the highest dietary fat intake [62]. In summary, analysis of the data suggests a positive but mild elevation of risk for colorectal neoplasia with high-fat diets.

A potential mechanism by which high-fat diets enhance tumor production appears related to stimulation of colonic epithelial proliferation by bile acids. In humans, increasing dietary levels of animal fat produces more total fecal bile acid and fatty acid excretion [63]. Colonic bacteria convert these compounds to secondary bile acids, cholesterol metabolites, and other possibly toxic substances. In animal models, rectal instillation of bile acids increases markers of cellular proliferation [64]. Additionally, bile acids can generate reactive oxygen radicals within the colon, independently stimulating mucosal proliferation.

Vegetables and fruits

Of all dietary associations with colorectal cancer, the correlation of high vegetable and fruit intake with low colorectal neoplasia risk appears the most convincing. About 75% of published case–control and cohort studies reveal a relative risk of less than 0.8 for colorectal neoplasia in subjects with the highest intake of vegetables and fruits [62]. An analysis of 37 observational epidemiological studies and metaanalysis from 16 case–control studies of vegetable intake and colon cancer found a combined OR of 0.48 (95% confidence limits [CI] 0.41–0.57) for the highest versus lowest quintiles of consumption [65]. A lowered risk of colon cancer has been particularly associated with raw, green, and cruciferous vegetables.

Vegetables and fruits contain a host of potentially antimutagenic compounds. These include isothiocyanates, monocyclic monoterpenoids (limonene, methol), retinoids, and flavonoids, which modulate xenobiotic metabolizing enzymes and inhibit promutagen activation. Retinoids and flavonoids also enhance cellular apoptosis. Provitamins and vitamins (i.e., β-carotene, ascorbic acid) are effective in scavenging reactive oxygen species. Dietary fiber is thought to inhibit mutagen uptake. Phenols, including cinnamic acid and chlorogenic acid, suppress endogenous formation of mutagens by inhibiting nitrosation. Other vitamins, including folic acid and B-12, and minerals such as selenium and zinc are thought to maintain genomic stability [66].

Fiber

The effect of dietary fiber on colorectal cancer risk is unclear. Fiber can be defined as ingested plant material that resists gastrointestinal digestion and is not absorbed or useful as a calorie source. Dietary fiber can be divided into four groups: cellulose, hemicelluloses, pectins, and lignins. The first three types are carbohydrates, whereas lignins are noncarbohydrate complex polymers that bind cellulose and strengthen plant cell walls. High-fiber foods include vegetables, fruits, grains, and nuts.

The first association between dietary fiber intake and decreased cancer risk was suggested by Burkitt in 1969 [67]. He proposed this hypothesis based on the observation that large bowel cancer, universally prevalent in the civilized world, was almost unknown in rural Africa. He connected this fact with differences in diet between these populations, particularly the removal of unabsorbable fiber by modern food processing. He further demonstrated that large bowel cancer was rare in communities whose members consumed high-fiber diets but lived in countries where a low-residue diet was the norm [68].

Numerous cohort and case–control studies have evaluated the hypotheses of an inverse relationship between dietary fiber intake and colorectal neoplasia. In general, about 60% of investigations provide support for this concept [62]. An analysis of 13 case–control studies, which estimated risks from pooled data, found a reduction in colorectal cancer risk with increasing intake of dietary fiber [69]. Another meta-analysis of 16 case–control studies reported similar findings [65]. In these studies, those taking the highest amounts of fiber had about a 45% lower risk of colorectal cancer compared with those taking the lowest amounts. A significant drawback of most investigations is the inability to adjust for other nonfiber dietary constituents, which may be confounding the interpretation. A large European prospective study of over 519 000 individuals found significant protection by high fiber intake [70]. The RR for colorectal cancer was 0.58 (95% CI 0.41–0.85) for the highest (32–36 g/day) versus lowest quintile (13.0 g/day) of fiber intake.

The proposed chemoprotective mechanisms of fiber include lumenal dilution and binding of toxic substances, decrease of colonic transit time with less mucosal contact time for fecal mutagens, and decreased colonic pH with potential inhibition of carcinogens. Also, fiber reduces the concentration of secondary bile acids, which have been noted to increase colorectal mucosal proliferation.

However, the inverse relationship between dietary fiber and colorectal cancer has been challenged by several large studies [49,71]. A prospective study of the association of fiber intake with the incidence of colorectal cancer included US data on over 76 000 women and 47 000 men, with repeated measures of diet. After adjustment for confounding variables, no association was noted [71].

Also, clinical trial data exist from two large prospective randomized controlled studies that attempted to decrease the incidence of recurrent colorectal adenomas in patients with previously removed adenomas using dietary fiber or dietary fiber plus low fat. In both trials no statistically significant effect was noted in the treatment versus the control groups [72,73].

Calcium

The concept of a protective effect of dietary calcium for colorectal cancer was first suggested by Newmark et al. in 1984 [74]. Since then, evidence from in vitro and animal investigations has supported this concept. In colon cell culture, increasing levels of calcium decrease cell proliferation and induce cell differentiation [75]. In numerous murine studies, calcium decreases markers of colorectal mucosal proliferation, decreases colonic mucosal hyperproliferation, and inhibits colonic tumor development [76].

Initially, epidemiological studies of calcium intake and colorectal cancer suggested little or no protection against colorectal cancer from this dietary constituent [77,78]. Subsequently, several prospective cohort and large case–control studies have reported a 15%–46% decrease of colorectal cancer in individuals in the highest versus the lowest intake groups [79–83]. Moreover, metaanalysis of three randomized clinical trials of calcium supplementation to prevent recurrent colorectal adenomatous polyps revealed an overall RR for recurrent polyps of 0.80 (95% CI 0.68–0.93) with the use of calcium [84]. The largest of these studies, involving 930 patients randomized to 3.0 g of calcium carbonate daily (1.2 g of elemental calcium) or placebo, demonstrated a 19% lower risk of recurrent polyps in those given calcium [85]. The protective effect of calcium is thought secondary to the ability of this element to inactivate injurious lumenal substances, including fatty acids and bile acids, by forming insoluble compounds with these agents. Lumenal calcium may affect colorectal tumors by means of the calcium-sensing receptor (CASR) located in the plasma membrane [86].

Folate

Folate is a B vitamin found in dark-green leafy vegetables (i.e., spinach and turnip greens), fruits (i.e., citrus fruits and juices), and dried beans and peas. In both in vitro and animal studies, folic acid has been implicated in DNA synthesis and repair, DNA methylation, and modulation of cell proliferation [87,88]. In murine models of colorectal cancer, folate administration has chemopreventive effects [89,90]. Generally, case–control studies evaluating the association between folate and risk for colorectal cancer (in which folate intake was assessed by food frequency questionnaire) give weak inverse associations. In some the protective effect of folate is greatly decreased or disappears when the analysis is adjusted for other nutrition factors [91–93].

Several large prospective cohort studies have evaluated the influence of folate on colorectal neoplasia. In the Nurses' Health and Health Professional follow-up studies, a decreased RR to develop colorectal adenomas was noted in both men (RR 0.63; 95% CI 0.41–0.98) and women (RR 0.66; 95% CI 0.46–0.95) with high versus low intake of folate [94]. Also, the risk of colorectal neoplasia was inversely related to folate intake for men (RR 0.40; CI 0.18–0.88) in the National Health and Nutrition Epidemiologic follow-up study [95], and in women (RR 0.25; 95% CI 0.13–0.51) in the Nurses' Health Study [96]. In the latter investigation, the marked risk reduction occurred in those taking folate supplements for at least 15 years.

Selenium

Selenium is a trace mineral required in small amounts for human health. Selenium is incorporated into proteins to make selenoproteins, which are antioxidant enzymes. Plant foods are the major dietary sources of selenium; the concentration of selenium in food correlates with the selenium content of the soil where plants are grown. In ecological studies selenium intake is associated with a protective effect against colorectal cancer [97]. Selenium inhibits growth in colorectal

cancer cell lines [98] and, in animal studies, this trace mineral consistently shows activity against colorectal cancer [99–102]. In the laboratory, selenium is noted to have effects on key cellular processes in oncogenesis including cell proliferation and apoptosis. Moreover, selenium may be involved in mechanisms of gene promoter methylation and polyunsaturated fatty acid metabolism [103].

The association between selenium and colorectal adenomas or cancer from epidemiological studies has been inconsistent. Some investigations note a statistically significant or suggestive protective relationship [104–110], and others a null or harmful correlation [111–116]. The strongest evidence for a colorectal chemopreventive effect of selenium comes from a randomized, placebo-controlled trial of 1312 individuals utilizing selenium to prevent skin cancer. This trial showed a decreased RR of the secondary endpoint, colorectal cancer (RR 0.58; 95% CI 0.18–0.95), in individuals in the selenium group [117]. A combined evaluation has been conducted of blood selenium concentrations from 1763 participants from three randomized colorectal adenoma prevention trials [118]. This analysis revealed that individuals whose blood selenium values were in the highest quartile had lower odds of developing a new adenoma compared with those in the lowest quartile (OR 0.66; 95% CI 0.50–0.87).

Vitamins

Vitamins A, β-carotene, and vitamin E have powerful antioxidant activity, and retinoids function in laboratory models as differentiating agents. Nevertheless, research provides no evidence that these vitamins reduce the risk of colorectal cancer [119]. Among the data is a large placebo-controlled trial of β-carotene, vitamin C, and vitamin E showing a lack of effect of these agents in preventing colorectal adenomas [120].

Hormones

Endogenous and exogenous sexual hormones play a role in the etiology of colorectal tumors. Observational evidence for this association includes the finding that nuns and nulliparous women are more susceptible to colorectal cancer development compared with women of higher parity, early age at first birth, and regular users of oral contraceptives [121,122]. There are mounting data to suggest that estrogen/progesterone treatment reduces the risk of colorectal cancer. A metaanalysis evaluated the association of oral contraceptives and colorectal cancer risk [123]. The pooled RR showed an 18% decreased risk of colorectal cancer for those ever using oral contraceptives (RR 0.82; 95% CI 0.74–0.92). Also, epidemiological data suggest a 20% reduction in the risk of colorectal cancer in women who had had hormonal treatment [124]. In addition, a randomized placebo-controlled trial of healthy women by the Women's Health Initiative revealed a 37% reduction in colorectal cancer risk in those on hormonal compounds (estrogen and progesterone) compared with the placebo group [125]. A follow-up publication by this group and data from others suggests that the progesterone rather than estrogen may be the more important factor in colorectal neoplasia reduction [126,127].

Nonsteroidal antiinflammatory drugs

Strong support for the protective effect of nonsteriodal antiinflammatory drugs (NSAIDs) against colorectal cancer is provided by four lines of evidence: in vitro experiments, animal studies, epidemiological observation, and clinical trials. This class of drugs, including sulindac sulfide, piroxicam, and indomethacin (indometacin), inhibit the proliferation of colon cancer cells in vitro [128–130]. Also, multiple experiments have been conducted with a variety of NSAIDs in carcinogen-induced and genetic murine models of colorectal cancer [131]. These studies reveal dramatic reductions in the multiplicity (size and number of tumors per animal) and incidence of intestinal neoplasia in the NSAID-treated animals compared with placebo controls.

Almost all case–control and cohort studies find an inverse relationship between NSAID use and colorectal cancer incidence or mortality [131]. Among these are several seminal publications [132,133]. Thun et al. evaluated the prospective mortality from colorectal cancer of 662 424 adults from an American Cancer Society database who provided information on their frequency and duration of aspirin usage [132]. The RR of colorectal cancer death was 0.60 in men (95% CI 0.40–0.89) and 0.58 (95% CI 0.37–0.90) in women who used aspirin 16 or more times a month compared with those without aspirin use. A dose–response relationship to colorectal cancer protection was also noted. Similar protective estimates of RR for colorectal incidence were reported in a study of a cohort of 89 446 women from the Nurses' Health Study [133]. This investigation adjusted for multiple variables including age, history of polyps, prior endoscopy, family history, diet, smoking, alcohol, and physical activity.

A number of clinical trials support the chemopreventive effect of NSAIDs against colorectal neoplasia. Initially, in a randomized double-blind placebo-controlled trial, sulindac, a commonly used NSAID, regressed existing colorectal adenomas in patients with familial adenomatous polyposis [134]. This finding was supported by additional similar studies utilizing sulindac [135,136] and celecoxib, a selective cyclooxygenase-2 (COX-2) inhibitor [137]. Subsequently several large randomized placebo-controlled trials of aspirin to prevent recurrent colorectal adenomas in those with a history of a sporadic adenoma [138,139] or previous colorectal cancer [140] have been conducted. All show a moderate (19%–35% reduction of recurrent adenomas) chemopreventive effect of aspirin on large bowel adenoma recurrence. By contrast, a large randomized placebo-controlled trial of 22 071 male physicians evaluated aspirin to prevent myocardial infarction and β-carotene to prevent cancer. Because of the marked effect of aspirin in decreasing the incidence of myocardial infarction the study was terminated prematurely.

Secondary analysis revealed no effect of aspirin, 325 mg every other day, on colorectal cancer incidence [141]. Reasons for a lack of a protective association in this trial may be the small dose and short duration of aspirin usage. Also, primary chemoprevention in familial adenomatous polyposis utilizing sulindac to prevent the development of the phenotypic emergence of polyposis was ineffective [142].

Nonsteroidal antiinflammatory drugs have inhibitory effects on the COX-1 and COX-2 enzymes, which are key in the conversion of arachidonic acid into prostaglandins (PGs). Most tissues contain COX-1, whereas COX-2 is expressed in response to growth factors, lipopolysacharide, cytokines, mitogens, and tumor promoters [143]. Prostaglandins are involved in cellular functions including angiogenesis and cell proliferation, and inhibition of PG synthesis could partially explain the antineoplastic effects of NSAIDs. Also, COX-2 inhibition has antiangiogenic [144,145] and apoptotic effects [146].

Several COX-2-independent targets for NSAIDs have been proposed. These include β-catenin, because both indomethacin and exisulind reduce β-catenin expression in colorectal cancer cells [147,148]. Also, NSAIDs induce apoptosis through both the membrane-bound and the mitochondrial pathway. High doses of aspirin antagonize the transcription factor NF-κB [149], which regulates expression of antiapoptotic genes encoding proteins such as TRAF, c-IAP, c-FLIP, Bcl-X_L and A1. Proteins of the Bcl-2 family and the membrane death receptor apoptotic pathway may also be involved in response to NSAIDs [150]. Furthermore, transforming growth factor-β (TGF-β) signaling is implicated in NSAID chemoprevention [151]. Also, NSAIDs affect cell adhesion [152] and lipoxygenase metabolism [153], which reduces cell invasion of colorectal cancer cells. Finally, it appears that the members of the peroxisome proliferator-activated receptor (PPAR) family, PPARδ and PPARγ, are directly targeted by NSAIDs and PGs [154].

Alcohol

A multitude of studies evaluating the role of alcohol in colorectal cancer reveal a positive association between colon cancer and alcohol drinking [62,155]. A pooled analysis of eight cohort studies from North America and Europe indicated that daily consumption of 45 g alcohol from any type of beverage increased the risk of colorectal cancer by 41% (RR 1.41; 95% CI 1.16–1.72) [156]. Data were published from the NHANES Epidemiologic Follow-up Study (NHEFS) consisting of 10 220 participants prospectively followed over a decade [157]. This study revealed that consumption of one or more alcoholic beverages a day was associated with about a 70% greater risk of colorectal cancer (RR 1.69; 95% CI 1.03–2.79), with most risk occurring in those drinking for more than 34 years. Compared with other investigations, this study noted increased risk only in those drinking liquor versus wine or beer.

Mechanisms by which alcohol might increase carcinogenesis include enhancing gastrointestinal cell regeneration, and depressing immune responses. Also, in the absence of adequate folic acid stores, ethanol enhances DNA methylation [157].

Smoking

Numerous studies of various designs reveal a positive association between smoking and the occurrence of colorectal cancer [158]. Almost all note a statistically significant association between colorectal adenomas – the precursor lesion for colorectal cancer – and long-term smoking. Although studies evaluating smokers in the 1950s and 1960s with short smoking exposure found no correlation with colorectal cancer, all investigations with follow-up times of four or more decades report an association. A dose–response relationship between colorectal cancer and cigarette smoking has consistently been reported. Evaluation of pooled data reveals that long-term heavy cigarette smokers have a two- to three-fold elevated risk for colorectal adenomas [158]. In a study from the Chicago Heart Association evaluating a cohort of 39 299 individuals, the RR of fatal colorectal cancer was 1.87 (95% CI 1.08–3.22) for those smoking more than 20 cigarettes a day compared with nonsmokers [159].

Physical activity

Physical activity is consistently associated with reduced risk of colon cancer. Data from a metaanalysis of 19 cohort studies showed a statistically significant reduction in the risk of colon cancer in physically active males (RR 0.79; 95% CI 0.72–0.87) and females (RR 0.71; 95% CI 0.57–0.88) [160]. Evaluation of case–control studies in this analysis showed significantly reduced risks of colon cancer in both genders, but no protection against rectal cancer in either gender. An evaluation of physical activity and colorectal cancer in the Cancer Prevention Cohort Study II Nutrition Cohort analyzing over 150 000 individuals supported this conclusion [161]. In this investigation, colon and rectal cancer risk decreased significantly with increasing total hours of physical activity.

Obesity

Literature from case–control and prospective cohort studies reveal a positive association between body mass index (BMI) and risk of colorectal neoplasia. A modest increased risk of colorectal cancer exists with a BMI above 30, associated with a two-fold increased risk of colorectal adenomas [162]. Central obesity, as measured by waist-to-hip ratio, is associated with an increased prevalence of colorectal adenomas and cancer.

Other

Among other proposed causes of colorectal cancer is the JC (John Cunningham) virus (JCV) [163]. This virus, a member of the polyomavirus family, contains one of the most potent oncogenes discovered, encoding a version of the T-antigen

(transforming antigen). Commonly present in the DNA extracted from neoplastic human colonic tissues, JCV is a transforming virus in several laboratory models, forms tumors when infected into the brains of rodents and monkeys, and is a potent cause of chromosomal instability (CIN), a common phenomenon in colorectal cancer. Humans are ubiquitously infected with JCV at a young age. The proposed carcinogenic mechanism is that the virus remains latent until some stimulus prompts viral activation with associated T-antigen stimulation, CIN, and genesis of colorectal cancer.

Inherited factors

Inherited predisposition is an important factor in a significant number of patients developing colorectal cancer. Although the majority (80%) with colorectal malignancy have sporadic disease with no evidence of an inherited disorder, the remaining 20% have a potentially definable heritable genetic abnormality. There are several well-described forms of inherited colorectal cancer including familial adenomatous polyposis (FAP) and hereditary nonpolyposis colorectal cancer (HNPCC) (Table 65.2). Also, germ-line mutations causing the harmatomous polyposis syndromes predispose individuals to colorectal cancer. Finally, additional germ-line mutations confer less dramatic but still increased risk to carriers.

Familial adenomatous polyposis

Familial adenomatous polyposis (FAP) is an autosomal dominant syndrome caused by germ-line mutation of the *APC* (adenomatous polyposis coli) gene [164]. This disorder is estimated to occur in at least 1 in 14 000 live births, has worldwide distribution, and affects both genders equally [165]. Affected individuals characteristically develop colorectal adenomatous polyposis (> 100 colorectal adenomas) in their teenage years. The mean age of polyposis development is 15 years [166,167]. If colectomy is not performed the lifetime risk of colorectal cancer is virtually 100% at an average age of diagnosis of 35–43 years [166,168].

In addition to colorectal adenomatous polyposis, patients with FAP can develop a host of benign extracolonic manifestations. These include cutaneous lesions (lipomas, fibromas, sebaceous and epidermoid cysts) [169], desmoid tumors [170], osteomas [171], occult radiopaque jaw lesions [172], dental abnormalities [173], pigmented ocular fundic lesions (congenital hypertrophy of the retinal pigment epithelium) [174], and nasopharyngeal angiofibroma [175]. Also, patients can have extracolonic polyps (adenomas of the small intestine and stomach, fundic gland retention polyps of the stomach) [176,177]. Extracolonic malignancies that can occur in those affected with FAP include hepatoblastoma [178], upper gastrointestinal tract malignancies (duodenum and periampullary area, rarely jejunum) [177,179], thyroid gland, biliary tree, pancreas [180], and brain [181].

The *APC* gene is located on chromosome 5q21, and mutations at this locus account for almost all cases of FAP [182]. The *APC* gene is a tumor suppressor gene comprising 15 exons encoding a 2843-amino acid protein. The APC protein has many important functions including cell adhesion, signal transduction, and transcriptional activation [183]. Although more than 300 mutations of the *APC* gene causing FAP have been reported, 10% of FAP patients have a mutation in codon 1309. Commercial genetic testing of the *APC* gene is the test of choice for confirming the diagnosis and screening family members for this syndrome.

Several genotype–phenotype correlations occur in this disorder. The most important is that mutations between codon 169 and 1393 result in classic FAP whereas mutations in the more 5′ and 3′ regions of the gene (at the extremes of the coding region) predispose to a milder phenotype called attenuated familial adenomatous polyposis (AFAP) [184–186]. The key characteristic of AFAP is oligopolyposis (< 100 adenomatous polyps), rather than polyposis, noted at clinical presentation. However, marked phenotypic variation in polyp number can exist within a pedigree. Also, these patients have a delayed onset of colorectal cancer, on average 12 years later than observed in classic FAP. Also, a plethora of upper tract lesions has been noted in some AFAP patients. The clinical management of FAP and AFAP is discussed in Chapter 63.

MYH-associated polyposis

MYH-associated polyposis is an autosomal recessive syndrome caused by biallelic germ-line mutation of the *MYH* gene [187–190]. Affected individuals can develop colorectal adenomatous polyposis or oligopolyposis (< 100 adenomas at presentation) at a young age, phenotypes indistinguishable from classic FAP or AFAP [190]. Also, extracolonic manifestations like those in FAP or AFAP can be noted in these patients. Biallelic mutations of the *MYH* gene may also be a cause of early-onset colorectal cancer in the absence of multiple colorectal adenomas [191]. The *MYH* (mutY homologue) gene is located on chromosome 1p and encodes a component of the base excision repair pathway involved in repair of oxidative damage to DNA [192]. Two specific mutations, Y165C and G382D, causing the MYH protein to have amino acid substitutions, are known to be associated with this disorder.

Although increased risk of colorectal cancer and polyposis with biallelic *MYH* gene mutations has been confirmed, the risk of colorectal neoplasia among monoallelic carriers is unclear. A Canadian population-based series of 1238 colorectal cancer patients and 1255 healthy controls noted an increased risk of colorectal cancer in monoallelic carriers (RR 1.54; 95% CI 1.10–2.16) [193].

Hereditary nonpolyposis colorectal cancer

Hereditary nonpolyposis colorectal cancer (HNPCC) is a syndrome known by several other appellations. These include Lynch syndrome, after Dr Henry Lynch who detailed this condition in 1966, and cancer family syndrome, the term he

Table 65.4 Features of hereditary nonpolyposis colorectal cancer

Accounts for 1%–3% of all colorectal cancers
Autosomal dominant inheritance
Caused by mutation in a mismatch repair gene (*hMLH1*, *hMSH2*, *hMSH6*, *hPMS2*)
Eighty percent lifetime risk of colorectal cancer in mutation carriers
Risk of colorectal cancer in second decade, mean age at diagnosis 44 years
Predominantly right (proximal to splenic flexure) colon cancers (60%–80%)
Absence of multiple colorectal adenomas (nonpolyposis)
Cancer histology poorly differentiated, abundant extracellular mucin and lymphoid peritumoral host response
Cancer DNA with high microsatellite instability (90% of cancers)
Extracolonic cancers:
Endometrial, stomach, small bowel, biliary tract, ovary, brain glioblastoma
Transitional cell carcinoma of ureter, urethra, bladder and renal pelvix, skin
Sebaceous neoplasms, keratoacanthomas
Diagnostic criteria – Amsterdam I and II criteria
Treatment with colectomy and ileorectal anastomosis
Improved colorectal cancer survival, stage for stage, than sporadic colorectal cancer
Metachronous risk of cancers 3%–5% per year

Table 65.5 Amsterdam I and II criteria for the diagnosis of hereditary nonpolyposis colorectal cancer (HNPCC)

Amsterdam I criteria

1. Three or more relatives with histologically verified colorectal cancer, one of whom is a first-degree relative of the other two: familial adenomatous polyposis should be excluded
2. Colorectal cancer involving at least two successive generations
3. One or more colorectal cancer cases diagnosed before the age of 50

Amsterdam II criteria

1. Three or more relatives with histologically verified HNPCC-associated cancer (colorectal, endometrial, small bowel, ureter, or renal pelvis), one of whom is a first-degree relative of the other two: familial adenomatous polyposis should be excluded
2. HNPCC-associated cancer involving at least two successive generations
3. One or more cancer cases diagnosed before the age of 50

used to describe the phenotype of the families in his publication [194]. Unlike FAP, in which colorectal cancer arises from colorectal adenomatous polyposis, in HNPCC colon malignancies arise usually from one or a few adenomas – hence the term "nonpolyposis" (Table 65.4).

It is an autosomal dominant condition caused by mutation of one of the mismatch repair (MMR) genes, and accounts for about 1%–3% of all colorectal cancers [195–197]. The lifetime risk of colorectal cancer in persons with an MMR gene mutation approaches 80%. The mean age of diagnosis of colorectal cancer in this syndrome is 44 years, but a wide range of age of diagnosis is noted; patients not infrequently present with colorectal malignancy in the second and third decades of life. The majority (60%–80%) of tumors in this condition are found in the right colon (proximal to the splenic flexure). By comparison, only 41%–44% of sporadic colorectal cancers are right-sided. Also, the adenoma–carcinoma sequence appears more rapid than in sporadic colorectal cancer. In those affected with HNPCC, the risk of metachronous colorectal cancer approaches 40% at 10 years from the diagnosis of the first colorectal malignancy; synchronous colorectal cancer is seen in 18% of patients [198]. Histologically, HNPCC colorectal cancers tend to be poorly differentiated, abundant in extracellular mucin, and distinguished by a lymphoid (peritumoral lymphocytes) host response to the tumor [198,199]. Some investigators report that HNPCC patients have improved 5-year survival from colorectal cancer, stage-for-stage, compared with individuals with sporadic colorectal malignancy.

Patients with HNPCC and their family members can develop a wide range of extracolonic malignancies, with the highest risk for endometrial cancer (40%–70% lifetime risk) [200,201]. Also, these patients are at increased risk for adenocarcinomas of the stomach, small bowel, biliary tract, ovary, glioblastoma of the brain, and transitional cell carcinoma of the ureter, urethra, bladder, and renal pelvis (lifetime risks for malignancies ranging from 2% to 13%). Most reported studies have not noted increased risks for lung, breast, hemopoietic, prostate, or larynx cancers in HNPCC kindreds. Café-au-lait spots, sebaceous gland tumors (adenomas and carcinomas), and keratoacanthomas (the latter two findings are hallmarks of the Muir–Torre variant of HNPCC) are the only reported clinical signs in HNPCC patients [202].

In 1990, the International Collaborative Group on Hereditary Nonpolyposis Colorectal Cancer established research (ICG) criteria for HNPCC [203] (Table 65.5). Better known as the Amsterdam I criteria, these standards are used for the clinical diagnosis of HNPCC. All of the following elements are required to diagnose HNPCC:

- one or more colorectal cancer cases diagnosed before the age of 50
- colorectal cancer involving at least two generations
- three or more relatives with histologically verified colorectal cancer, one of whom is a first-degree relative of the other two (FAP should be excluded).

Some physicians felt these standards were too stringent for clinical application, and alternative criteria (Amsterdam II criteria) were proposed (Table 65.5). Amsterdam II criteria include extracolonic tumor types commonly observed in HNPCC, such as cancer of the endometrium, upper gastrointestinal tract, and urinary tract [204].

The cause of HNPCC is mutation in one of four DNA mismatch repair (MMR) genes. The MMR genes, first discovered in yeast, maintain fidelity of DNA during cellular replication by correcting nucleotide base mispairs and small insertions or deletions generated by misincorporations or slippage of DNA polymerase. Mutations in the following MMR genes cause HNPCC: *hMSH2* (human mutS homologue 2) on chromosome 2p16 [205,206]; *hMLH1* (human mutL homologue 1) on chromosome 3p21 [207,208]; *hPMS2* (human postmeiotic segregation 2) on chromosome 7q11 [209]; and *hMSH6* (human mutS homologue 6) on chromosome 2p16 [210,211]. Germ-line mutations of *hMSH2* and *hMLH1* account for more than 90% of the mutations found in HNPCC families [212]. Insufficient evidence exists to implicate mutations in *hPMS1* or *hMLH3* as causing HNPCC.

Microsatellite instability (MSI) affects the DNA of colorectal cancer cells of individuals with germ-line MMR gene mutations but not in the patient's adjacent normal colorectal mucosa. In HNPCC patients diagnosed by Amsterdam I criteria, MSI is found in 90% of colon tumors, compared with 15%–20% of individuals with sporadic colorectal cancers [213]. Microsatellite instability is characterized by expansion or contraction of short repeated DNA sequences (i.e., microsatellite repeats) as a result of insertion or deletion of repeated base pairs. The presence of this phenomenon indicates probable defects in the MMR genes because of somatic changes, or it can suggest a germ-line mutation, that is, the diagnosis of HNPCC [214]. Developed in 1997 and revised in 2004, the Bethesda [215] and Revised Bethesda criteria [216], respectively, propose indications for the clinical use of MSI tumor analysis (Table 65.6). It has been reported that MSI, as a marker for the MMR pathway of colorectal neoplasia, is associated with improved survival, stage-for-stage, in sporadic patients with MSI-positive tumors [217].

Several genotype–phenotype correlations occur in HNPCC. First, Muir–Torre syndrome, a rare variant of HNPCC, is diagnosed in patients with HNPCC and skin sebaceous gland neoplasms (sebaceous adenomas, epithelioma, carcinomas) or keratoacanthomas. Microsatellite instability can be found in the DNA of skin tumors and colorectal tumors of affected patients [218]. Mutations of *hMSH2* are most often found in those with identified germ-line alterations of the MMR genes [219]. Second, patients with mutation of the *MSH6* gene have an "attenuated" form of HNPCC. Carriers of *hMSH6* mutations appear to have less risk for all HNPCC-related tumors (with one exception) than patients with alterations of the *MLH1* or *MSH2* genes. In one study of *hMSH6* carriers, the cumulative risk for colorectal cancer was 69% in males and 30% in females (80% in other MMR gene mutation carriers) at 70 years of age. However, endometrial cancer risk was higher (71%) in those with *MSH6* mutations (40% in others MMR gene carries) [220]. Third, Trimbath syndrome defines patients with homozygous mutations of the MMR genes, such as *hPMS2* or *hMLH1*. These patients are characterized by café-au-lait spots, early onset of colorectal neoplasia (in teenage years), oligopolyposis, glioblastoma at a young age, and lymphoma [202].

Table 65.6 Revised Bethesda guidelines for microsatellite instability testing of colorectal tumors

1. Colorectal cancer diagnosed in a patient less than 50 years of age
2. Presence of synchronous or metachronous colorectal, or other HNPCC-associated tumors, regardless of age[a]
3. Colorectal cancer with the MSI-H[b] histology[c] diagnosed in a patient less than 60 years of age
4. Colorectal cancer diagnosed in one or more first-degree relatives with an HNPCC-related tumor, with one of the cancers being diagnosed under age 50 years
5. Colorectal cancer diagnosed in two or more first- or second-degree relatives with HNPCC-related tumors, regardless of age

a Colorectal, endometrial, stomach, small bowel, ovarian, pancreas, ureter and renal pelvis, biliary tract, and brain (usually glioblastoma) cancers, and sebaceous gland neoplasms (carcinomas, adenomas) and keratoacanthomas.
b MSI-H, microsatellite instability-high; tumors with changes in two or more of the five National Cancer Institute-recommended panels of microsatellite markers.
c Presence of tumor-infiltrating lymphocytes, Crohn's-like lymphocytic reaction, mucinous/signet-ring differentiation, or medullary growth pattern.

Screening

Consensus opinion has formulated recommendations for colorectal screening in HNPCC. In the absence of genetic testing, first-degree relatives of affected individuals are advised to undergo colonoscopy every 1–2 years, starting between 20 and 30 years of age, and annually after 40 years of age [221], or alternatively every 1–2 years, beginning at age 20–25 years, or 10 years younger than the youngest age at colorectal carcinoma (CRC) diagnosis in the family, whatever comes first [222]. Individuals with germ-line mutations are recommended to have colonoscopy annually. Because of associated risk for endometrial and ovarian cancer, annual screening in women beginning at age 25–35 years is recommended, with consideration of transvaginal ultrasound (with or without CA-125) and endometrial biopsy [222]. The efficiency of gynecological screening remains uncertain. In families with a predilection for gastric and urological tumors, consideration should be given to upper endoscopy, urine analysis, and urine cytology.

When possible, genetic testing for HNPCC is recommended for screening individuals over the age of 18 years [222–224]. Screening begins by testing an affected member of the family to identify the pedigree mutation. Microsatellite testing is indicated for patients who meet the Revised Bethesda criteria.

Microsatellite instability testing or immunohistochemical (IHC) analysis for MMR gene proteins is performed on the tumor tissue of individuals putatively affected with HNPCC. A result of MSI-high (two or more microsatellite markers positive out of five tested) or absence of a specific gene protein in tumor DNA IHC analysis suggests the presence of a germ-line MMR gene mutation and prompts patient germline testing. Commercial testing by sequencing and analysis for large gene segment rearrangement is available for the *hMSH2*, *hML1*, and *hMSH6* genes.

Treatment

Because of the high rate of metachronous colorectal cancer, subtotal colectomy with ileorectal anastomosis (and postsurgical endoscopic rectal surveillance) is recommended when colorectal cancer develops in the setting of HNPCC [223,225]. There is no consensus regarding prophylactic surgery of the colon, uterus, and ovaries for MMR gene mutation carriers, but this should be considered on an individual patient basis [225].

Other genetic factors

Discovered in 1997, the I1307K mutation of the *APC* gene is one cause of familial colorectal cancer [21]. This mutation forms an unstable polyadenine tract in the *APC* gene that confuses the DNA replication machinery, resulting in susceptibility to additional somatic mutations elsewhere on the same allele of the *APC* gene during cell division. Found in 6%–8% of Ashkenazi Jews, and in 1%–4.7% of non-Ashkenazi Jews, this mutation doubles the lifetime risk of colorectal cancer in gene mutation carriers [21,226].

In 1999, genetic linkage and mutational analysis was performed in investigating a pedigree with multiple members with colorectal adenomas, serrated colorectal adenomas, or cancer. Evidence was uncovered for a new colorectal cancer susceptibility gene, *CRAC1* (colorectal adenoma and carcinoma), mapping to chromosome 15q14-q22 [227]. Further investigation is necessary to understand the clinical significance of this genetic locus.

Additional candidates for low-penetrance susceptibility alleles for colorectal cancer include the protooncogene Harvey Ras-1 variable number tandem repeat (HRAS1-VNTR) and the methylation gene 5,10-methylenetetrahydrofolate reductase (*MTHFR*) [228]. Also, epigenetic abnormalities associated with increased cancer risk include loss of imprinting of the insulin-like growth factor gene 2 (IGF2), which has been associated with a 22-fold increased risk of colorectal cancer in those affected [229].

Other syndromes associated with colorectal cancer

(see also Chapters 63 and 64)

Peutz–Jeghers syndrome (PJS) is an autosomal dominant syndrome characterized by labial melanin pigmention and hamartomatous Peutz–Jeghers polyps primarily in the small intestine. This syndrome is cause by mutation of the *STK11* (*LKB1*) gene in up to 70% of affected individuals. Patients with PJS have a strikingly high (39%) lifetime risk of colorectal cancer and of a wide variety of other gastrointestinal and nongastrointestinal tumors [230,231].

Juvenile polyposis primarily affects the large intestine and is diagnosed in patients with five or more colorectal juvenile polyps, but affected individuals can have polyps throughout the gastrointestinal tract. Mutations of the *BMPR1A* and *SMAD4* genes are found in 25% and 20% of cases, respectively. The lifetime risk of colorectal cancer in these patients has been estimated by case series to be 17%–68% [232], and in a person-year analysis to be 39% [233].

Cowden syndrome and a variant, Bannayan–Riley–Ruvalcaba syndrome, are two additional inherited conditions associated with the development of colorectal hamartomatous polyps. Up to 80% of individuals with these syndromes have mutation of the *PTEN* (*MMAC1*) gene found on chromosome 10. The risk of colorectal cancer in these syndromes is thought to be slightly higher (9%) than that in the general population [234].

Family history of colorectal neoplasia

Of all patients with colorectal cancer, the known genetic syndromes constitute 3%–5%. However, familial clustering of colorectal cancer is noted in the pedigrees of about 20% of affected patients, suggesting that other inherited genetic abnormalities have yet to be discovered. Systematic reviews of studies of family history (excluding known genetic syndromes) and colorectal cancer risk note several findings. First, the risk of colorectal cancer is closely related to younger age at diagnosis and greater number of affected relatives. Second, familial risk of colorectal cancer is greater in relatives of colon cases rather than rectal cases. Finally, colorectal cancer in these familial colorectal cancer pedigrees has no predominant location, compared with HNPCC, which is characterized by right-sided lesions.

Over 30 case–control and cohort studies have evaluated family colorectal cancer risk. Metaanalysis of these reports estimated the RR for colorectal cancer in an unaffected family member with one affected first-degree relative to be 2.25 (95% CI 2.00–2.53) [235]; the RR for colon cancer was somewhat higher than for rectal cancer, at 2.42 (95% CI 2.20–2.65) versus 1.89 (95% CI 1.62–2.21), respectively. Both types of first-degree relatives were found to be at increased risk, but the RR for siblings, at 2.57 (95% CI 2.19–3.02), was somewhat higher than the 2.26 (95% Cl 1.96–2.59) for parent–child relationships. The RR for individuals with a first-degree relative diagnosed before age 45 was 3.87 (95% CI 2.40–6.22), between ages 45 and 59 was 2.25 (95% CI 1.85–2.72), and after age 59 was 1.82 (95% CI 1.47–2.25). The RR for colorectal cancer when two or more first-degree relative were affected was 4.25 (95% CI 3.01–6.02).

The increased risk of CRC in an unaffected family member is also associated with adenoma in a first-degree relative, with a RR of 1.99 (95% CI 1.55–2.55), and is influenced by their age at diagnosis of the adenoma. The risk of colorectal cancer among family members increases with decreasing age at diagnosis of adenoma in the index case (2.6–4.4-fold higher if the adenoma is diagnosed before age 60 rather than at or after 60 years of age) [236,237].

Other risk factors

Previous history of colorectal cancer or adenomas

Patients with colorectal cancer have increased risk for synchronous (simultaneous) or metachronous (subsequent) colorectal malignancies. Prospective and retrospective studies in patients with sporadic colorectal cancer estimate the frequency of synchronous lesions at 3.5% [238–240]. Metachronous tumors, defined as cancer diagnosed more than 6 months after surgery for the index cancers, occurs at about a 0.6% per year. About 50% of metachronous lesions arise within 5–7 years of the first lesion.

Inflammatory bowel disease

Patients with inflammatory bowel disease (IBD), both ulcerative colitis and Crohn's disease (specifically Crohn's colitis), are at increased risk for colorectal cancer [241–244]. Although IBD patients account for a small percentage (1%–2%) of all cases of colorectal cancer diagnosed annually, this neoplasm is the cause of death in one of six persons with IBD [243,245].

The risk of colorectal neoplasia is best described in ulcerative colitis. Nevertheless, estimates of colorectal neoplasia in this population have varied secondary to the population studied (community vs referral center), rate of surgical resection, and use of antiinflammatory agents that may be chemopreventive. Most data suggest that the risk of colorectal cancer increases by 0.5%–1.0% yearly, starting 8–10 years after diagnosis of IBD [245,246]. Also, the mean age of colorectal cancer diagnosis in IBD patients is younger (40–50 years old) than for sporadic colorectal cancer (64 years old). In a metaanalysis of 116 studies, the prevalence of colorectal cancer in any ulcerative colitis patient was estimated to be 3.7% (95% CI 3.2%–4.2%) overall and 5.4% (95% CI 4.4%–6.5%) for those with pancolitis. The cumulative probabilities of colorectal cancer were 2%, 8%, and 18% after 10, 20, and 30 years of disease, respectively [246]. Factors that increase CRC risk include long duration of colitis, extensive colonic involvement, family history of colorectal cancer, primary sclerosing cholangitis, and young age at IBD diagnosis [247]. Other possible risk factors include the presence of backwash ileitis and the severity of inflammation [247]. Of note, patients with active colitis and those in remission are equally at risk for colorectal cancer.

Patients with Crohn's colitis are also at increased risk for colorectal cancer compared with the general population. In one study, the RR of colorectal cancer in patients with extensive Crohn's colitis was 18 times that of the general population and similar to an identically selected cohort of ulcerative colitis patients (19 times the general population risk) [248]. The absolute cumulative frequency of risk for developing CRC in Crohn's was 8% at 22 years from onset of symptoms. Other studies of relative risk of colorectal cancer in Crohn's disease have ranged from 0.89 to 5.6 times the general population [241,249]. Previous investigations noting lower colorectal cancer risks have included patients with ileitis or failed to account for extent or duration disease. Several studies have noted an increased risk of small bowel cancer in Crohn's disease with RRs up to 66 times that in the general population [250].

The characteristics of colorectal cancer are similar in ulcerative colitis and Crohn's disease. Respectively, cancers in both disorders occurred at a median of 15 and 18 years after onset of IBD, were multiple in 11% and 12%, occurred in the setting of dysplasia in 72% and 79%, and 5-year survival was 46% and 50% [243].

The risk of colorectal cancer in IBD can be minimized by two main strategies: colectomy and lifelong surveillance. Colectomy is more appropriately applied to patients with ulcerative colitis, and total protocolectomy is the usual surgical recommendation.

Chemoprevention may also be a useful tactic to decrease the risk of colorectal neoplasia in IBD patients. Several compounds have been investigated. First, NSAIDs decrease the risk of sporadic colorectal neoplasia (see "Nonsteroidal antiinflammatory drugs" above). Some studies [251,252], but not all [253], have noted a protective effect of 5-acetylsalicylic acid (5-ASA) compounds against colorectal neoplasia in ulcerative colitis patients. Second, low folate intake has been associated with an increased risk for sporadic colorectal adenomas and carcinomas. Patients with IBD are prone to folate deficiency as a consequence of inadequate nutritional intake and intestinal losses in the setting of active inflammation. Also, sulfasalazine, often used as a chemotherapeutic agent, is a competitive inhibitor of folate absorption. Three studies report protection against CRC in folate users, although none had statistically significant results [253–255]. Finally, ursodeoxycholic acid is a dihydroxy bile acid found in small quantities in human bile. Use of this agent was associated with a decreased prevalence of colonic dysplasia in patients with primary sclerosing cholangitis and ulcerative colitis [256]. Moreover, in this patient population, a randomized placebo-controlled trial of ursodeoxycholic acid noted a 73% decrease in colorectal cancer and dysplasia in the treatment group compared with the control group [257].

Diabetes

Investigators have noted that obesity, a Western-style diet, and lack of physical activity are common risk factors for both type 2 diabetes and colorectal cancer. Accumulating evidence suggests that type 2 diabetes is associated with an

increased risk of colorectal cancer [258,259] A study of the Iowa Cancer Registry noted, after adjustment for age, body mass index, and other potential confounders, a RR of colorectal cancer of 1.4 (95% CI 1.1–1.8) for women with diabetes compared with nondiabetics. An elevated risk was noted for tumors of the proximal colon, whereas risks for the distal colon and rectum were not different from unity [260]. Interestingly, no association has been found between colorectal cancer and type 1 diabetes or gestational diabetes. Potential mechanisms of increased risk include hyperinsulinemic stimulation of cell proliferation by activation of the insulin receptor or insulin-like growth factor (IGF) receptor, or through inhibition of IGF-binding proteins resulting in increased bioavailability of IGF-1 to the IGF-1 receptor [261].

Acromegaly

The association between acromegaly and colorectal neoplasia has been a subject of debate for many years. However, almost all of the colonoscopy-based prevalence studies reveal an increased risk of colorectal adenomas in these patients. An Italian multicenter colonoscopic screening and follow-up study reported that patients with acromegaly had an OR of 1.7 (95% CI 1.1–2.5) for colonic adenomas and 4.9 (95% CI 1.1–22.4) for colorectal cancer [262]. Also, a metaanalysis of three population-based studies estimated a pooled risk ratio of 2.14 (95% CI 1.32–3.14) for colorectal cancer [263].

Streptococcus bovis

The association between *Streptococcus bovis* bacteremia and colonic neoplasia has been documented by case reports and a case–control study [264–266]. The point prevalence of colorectal neoplasia in patients with *S. bovis* bacteremia ranges from 6% to 71%, with most of the 21 individual studies reviewed reporting a greater than 25% risk. One case–control series found that colonic adenomas were present in twice as many cases as controls, and colorectal cancer was present approximately three times as often. The reason for this association is unclear. One theory is that colonic neoplasia enables overgrowth and translocation of these organisms [265]; other theories suggest that *S. bovis* is a causative factor [267]. On the basis of the above data, several investigators have recommended that all patients with *S. bovis* infection have evaluation of the colon.

Dermatomyositis

Dermatomyositis and polymyositis appear to be associated with an increased risk of a wide range of malignancies [268,269]. The concurrent onset and parallel course of these rheumatological disorders and colorectal cancer suggests a close relationship. Moreover, a pooled analysis of published national data from Sweden, Denmark, and Finland revealed that individuals with dermatomyositis had a 2.5-fold (95% CI 1.4–4.4) increased risk of colorectal cancer compared with the general populations of those nations [269].

Gynecological cancers

Evaluation of the risk of subsequent colorectal cancer in patients with cervical, uterine, and ovarian cancer was accomplished by retrospective cohort analysis of the SEER (Surveillance, Epidemiology, and End Results) database from 1974 to 1995 [270]. In this study the overall risk for colorectal cancer was elevated not only in patients with ovarian cancer diagnosed before the age of 50 years (standardized incidence ratio [SIR] 3.67; 95% CI 2.74–4.80) but also for those who were 50–64 years old at diagnosis (SIR 1.25; 95% CI 1.25–1.83). Patients with prior onset of uterine cancer before the age of 50 had an elevated risk for colorectal cancer (SIR 3.39; 95% CI 2.73–4.17), but not those older when diagnosed with uterine cancer. There was no increased risk for colorectal cancer in those with cervical cancer.

Therapeutic interventions

Therapeutic interventions have been implicated in the genesis of colorectal cancer. Radiation therapy for prostate cancer was noted to increase the risk of rectal cancer by 70% (hazard ratio 1.7; 95% CI 1.4–2.2) in a retrospective cohort analysis of the SEER registry data [271]. Most work describes a modest association between cholecystectomy and colorectal cancer. After adjustment for other risk factors, RR for the association of cholecystectomy and colorectal cancer was 1.21 (95% CI 1.01–1.46) in an evaluation of the Nurses' Health Study cohort [272]. Often forgotten is the risk of neoplasms at the anastomosis of the ureter and large bowel in patients with ureterosigmoidostomies or one of the variations such as the Mainz II or Mansoura operations. The risk of neoplasia appears to increase 10 years after the operation, and is estimated as high as 24% at 20 years of follow-up [273].

Pathogenesis

General concepts

Since the 1990s, intense investigation of colorectal carcinogenesis has led to the discovery of seminal concepts concerning the mechanism of oncogenesis. Summed up in a single sentence, "Cancer is, in essence, a genetic disease" [274]. Colorectal cancer arises through a process beginning with normal colorectal mucosa, then progressing to single histological crypt lesions (aberrant crypt foci), then colorectal adenoma, and finally colorectal adenocarcinoma, by a multistep process driven by mutations at multiple chromosomal loci (Fig. 65.3). In sporadic colorectal cancer, no one gene mutation causes malignancy, and consequently mutations contribute to rather than cause colorectal cancer. In general, solid tumors accumulate between three and eight key mutations in the progression to malignancy. Evidence shows that nearly all colorectal cancers arise from adenomatous polyps. In sporadic colorectal cancer, the dwell time – time from

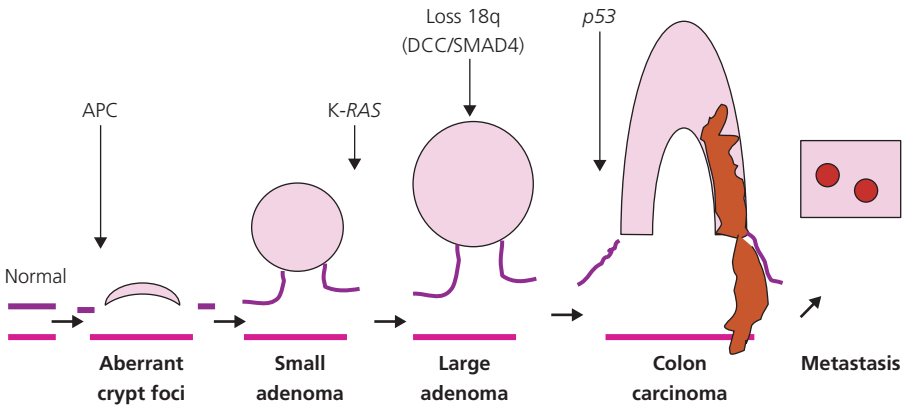

Figure 65.3 Chromosomal instability pathway of the adenoma–carcinoma sequence with particular genetic alterations arising at specific points.

adenoma to carcinoma – is estimated to be about 10 years. As acquired mutations accumulate in colorectal epithelium, they affect growth-regulating genes, thereby enhancing cell survival by increasing cell proliferation or preventing programmed cell death (apoptosis). The prevailing concept involves mutations occurring over time, with each engendering a clonal expansion resulting in large number of cells that form a substrate for subsequent mutations [274,275]. This paradigm of progression from adenoma to colorectal carcinoma driven by multiple somatic genetic mutations was first espoused by Fearon and Vogelstein in 1990 [276].

Alterations in several types of genes, including oncogenes, tumor suppressor genes, and stability genes, are responsible for colorectal carcinogenesis. Oncogenes generally drive the cell cycle, and when mutated become constitutively active or active under conditions in which the wild-type gene is quiescent. A somatic mutation in one allele of an oncogene is generally sufficient to give a selective growth advantage to the cell. Tumor suppressor genes normally function to retard tumor development. When these genes are mutated the activity of the gene product is reduced. Usually mutations in both alleles of the tumor suppressor gene are required to produce a selective growth advantage in the cell. Stability genes are responsible for repairing mistakes made during normal DNA replication or induced by mutagens. When these genes are inactivated, mutations in other genes occur at a higher rate. As with tumor suppressor genes, both maternal and paternal alleles must be inactivated before an aberrant effect is noted. The process of carcinogenesis is initiated when a competent stem cell acquires a mutation in a gatekeeping gene the endows the cell with a selective growth advantage.

Mechanisms of colorectal carcinogenesis

Genetic alterations can occur through several mechanisms including chromosomal instability, microsatellite instability, and methylation (Fig. 65.4). Chromosomal instability involves

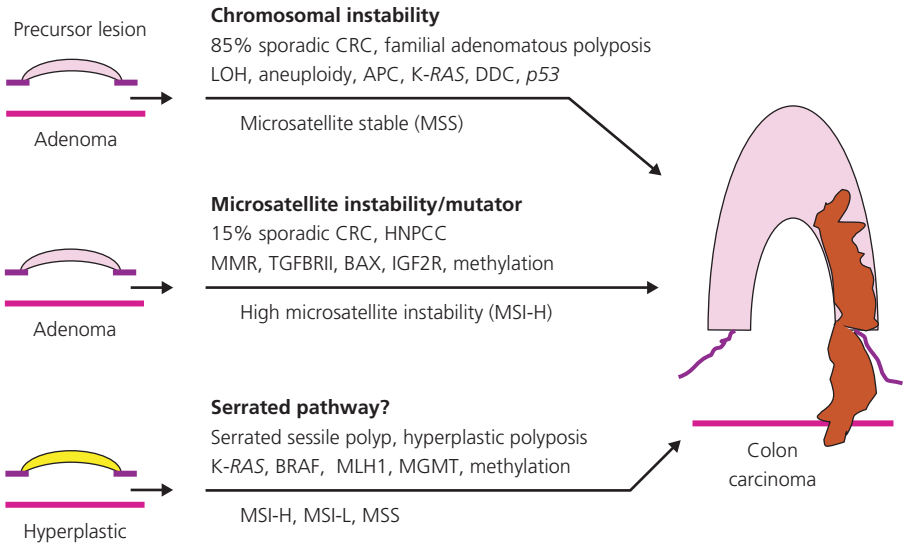

Figure 65.4 Postulated molecular pathways to colorectal cancer: chromosomal instability pathway; microsatellite instability/mutator pathway; and possibly the serrated pathway. Each pathway starts with a precursor lesion (adenoma or serrated sessile polyp), features a particular molecular mechanism (chromosomal instability, microsatellite instability, methylation), involves particular genes, and may be associated with a specific human phenotype of disease. The presence or absence of microsatellite instability in tumor tissue is noted for each pathway.

the loss of entire portions of a chromosome leading to alternations of specific genes and abnormal amounts of DNA per cell (aneuploidy). Microsatellite instability, a process in which there are mutations in the linear extent of tandemly repeated DNA sequences, is also evident in colorectal tumor tissue. Methylation is an epigenetic phenomenon that alters gene transcription.

Chromosomal instability (CIN)

The prototype pathway for colorectal carcinogensis is typified by chromosomal instability (CIN). Chromosomal instability is typified by losses and gains of whole chromosomes or large chromosomal regions in tumor tissue leading to alterations of specific genes and abnormal amounts of DNA per cell (aneuploidy) (Fig. 65.4). If the other, wild-type, allele of a corresponding gene is affected by somatic mutation, the result is inactivation of both copies of a particular gene (loss of heterozygosity, or LOH). Chromosomal instability results in a series of somatic mutations in key genes, as discussed below, and, thereby drives colorectal carcinogenesis. This mechanism seems to operate in a majority (80%) of colorectal tumors. Interestingly, CIN can be transferred in a dominant manner in cell fusion experiments and is associated with functional defects of mitotic checkpoints [277,278].

Although there are several inherited predispositions to colorectal cancer (including germ-line mutations in the MMR genes causing HNPCC, and in the *APC* gene leading to FAP), the majority of mutations contributing to colorectal cancer are acquired (somatic) in the tumor cell. Over a dozen genes are noted to be somatically mutated in colorectal cancer, but four specific gene alterations are particularly common in colorectal tumorigenesis. These include activation of RAS oncogenes and inactivation of tumor suppressor genes on chromosome 5q (*APC*), 17p (*p53*), and 18q (*DCC*, *SMAD4* [*DPC4*], and *SMAD2*) (Fig. 65.3).

APC *gene*

The *APC* gene is considered the gatekeeper gene in the colorectal adenoma–carcinoma sequence. This gene was discovered through investigation of pedigrees with FAP in which germ-line mutation of the *APC* gene caused the syndrome. Mutations in the *APC* gene are the earliest genetic event identified in the adenoma–carcinoma sequence, being found in microscopic aberrant crypt foci and in up to 80% of adenomas and carcinomas [279]. The *APC* gene is a tumor suppressor gene that plays a critical role in the WNT signal pathway [280]. The normal wild-type *APC* gene facilitates the degradation of β-catenin and, thereby, inhibits β-catenin/T-cell factor (TCF)-mediated transcription. However, mutation of the *APC* gene results an ineffective APC protein, which fails to degrade β-catenin, resulting in persistently elevated levels of cytoplasmic and nuclear β-catenin, which in turn provoke transcription of growth-promoting genes including the *MYC* oncogene. Mutations that activate the β-catenin gene are noted in the majority of colorectal tumors lacking an *APC* gene mutation, emphasizing the importance of the WNT pathway in colorectal carcinogenesis [281]. Other potential functions of the wild-type *APC* gene include regulation of cell apoptosis and cell–cell adhesion.

RAS oncogenes

The RAS genes were initially identified as the transforming components of the Kirsten and Harvey rat sarcoma virus genomes. Later, RAS genes with mutations were noted to transform cells in tissue culture [282,283]. RAS mutations are acquired during an intermediate stage of the colorectal adenoma–carcinoma progression. Mutations of *KRAS* or *NRAS* are rarely found in adenomas less than a 1.0 cm in size but appear in about 50% of all adenomas greater than 1.0 cm, and in adenocarcinomas [279]. About 85% of mutations identified are in codons 12 and 13 of the *KRAS* (Kirsten RAS) protooncogene, with some in the *NRAS* (neuroblastoma RAS) gene. The *KRAS* gene encodes a GTP-binding protein ($p21^{RAS}$), which is involved in the transduction of mitogenic signals across the cell membrane. When activated, KRAS exchanges guanosine diphosphate (GDP) for guanosine triphosphate (GTP) and initiates a signal cascade that triggers specific transcriptional factors. Mutation in the gene results in unchecked continued signal transduction and concomitant cellular growth advantage. Investigation reveals that colorectal tumors can develop in the absence of RAS mutations, or fail to progress in the presence of RAS mutations, and that preexisting *APC* mutations are important for neoplastic progression in the setting of a *KRAS* mutation.

Chromosome 18q

Initial studies revealed that about 70% of primary colorectal cancers had LOH for chromosome 18q, suggesting the existence of a novel tumor suppressor gene(s) at this location [279,284]. Further investigation noted that allelic losses of 18q were infrequent in small adenomas but common in colorectal carcinomas and almost all hepatic metastatic lesions [279,285]. This implied that LOH of 18q contributes to progression and acts at the intermediate to late adenoma stage rather than at the initiation of colorectal cancer. Investigators subsequently identified the *DCC* (deleted in colorectal cancer) gene, a large gene comprising 1.2 million base pairs, on chromosome 18q21 [284]. The DCC protein is a transmembrane receptor for netrins, key factors in axon guidance in the developing nervous system. Additional data suggest that DCC may be important in colorectal epithelial development by activating downstream signaling pathways involving the RAC1 protein and the extracellular signal-regulated kinase (ERK-1/2)-dependent pathways [286]. Also, DCC can induce active signaling of cell death by means of the caspase cleavage of DCC and the interaction of caspase-9 [286]. In several studies, somatic loss of *DCC* expression in colorectal cancers has been linked with poor patient prognosis and

increased risk of metastatic disease, suggesting the importance of this gene [287,288]. Additional candidate suppressor genes mapped to chromosome 18q include the *SMAD4* (mothers against decapentaplegic homologue 4) gene (formerly known as *DPC4*, deleted in pancreatic cancer 4), and *SMAD2* [289,290]. The *SMAD4* gene encodes a protein implicated in the signaling pathway of the TGF-β superfamily of signaling polypeptides [291]. However, based on present knowledge, one would argue that more tumor suppressor genes on chromosome 18q await discovery.

The p53 *gene*

Identified in 1979, the *p53* (*TP53*) gene was discovered following the observation that it was expressed in cells infected with tumor virus [292]. Located on chromosome 17p, the wild-type *p53* gene is a tumor suppressor gene with the function of stopping cell growth, when induced by stress conditions, through mechanisms including cell-cycle arrest or apoptosis. The *p53* gene encodes a 393-amino acid phosphoprotein that binds to specific sequences within the promoters of growth-inhibiting genes and activates their transcription [293]. Loss of function of this gene appears to conform to the Knudson two-hit hypothesis of gene inactivation [294]. One copy of the *p53* gene becomes defunct by loss of chromosome 17p13, the other by somatic mutation [295]. Loss of *p53* activity leads to a subsequent decrease in expression of growth-inhibiting genes, and hence a selective cellular growth advantage. The *p53* gene is thought to be involved in the transcriptional regulation of over 20 different genes with functions including apoptosis and cell-cycle arrest. Among the best described mechanisms of p53 action is the induction of expression of $p21^{WAF1/CIP1}$, which in turn causes G1 and G2 cell-cycle arrest [296]. The *p53* gene is commonly mutated in a variety of other human tumors including lung, breast, brain, bladder, and liver, emphasizing a central role for this wild-type gene in the prevention of carcinogenesis [297].

Chromosome 17p

Loss of chromosome 17p sequences are the most consistently observed molecular abnormality in colorectal carcinogenesis. Although seldom found in adenomas, loss of 17p is noted in 75% of carcinomas [279]. Also, *p53* mutations are noted in 50% of adenomas with high-grade dysplasia. These findings and others suggest that loss of *p53* gene function is crucial to the transformation from premalignancy (adenoma) to malignancy (adenocarcinoma), and occurs late in this sequence.

Microsatellite instability

Another mechanism of genetic instability is microsatellite instability (MSI) [298]. This phenomenon is noted in DNA analysis of approximately 15%–20% of all colorectal tumors [197] (Fig. 65.4). Microsatellite instability is characterized by unusual expansion or contraction of short repeated DNA sequences (i.e., microsatellite repeats) that are normally found in DNA. These changes in microsatellite length are caused by insertion or deletion of repeated units. This instability, known as "mutator phenotype," "replication error," or "microsatellite instability," indicates probable defects in the MMR genes. The MMR genes (*hMLH1*, *hMSH2*, *hMSH6*, *PM1S*, *hPMS2*) function to maintain fidelity of DNA during replication by correcting nucleotide base mispairs and small insertions or deletions generated by misincorporations or slippage of DNA polymerase. About 11% of patients with MSI found in tumor analysis have a germ-line mutation of a MMR gene and, thereby, are affected with HNPCC (see "Hereditary nonpolyposis colorectal carcinoma" above) [197]. However, the majority of individuals with this tumor phenotype have somatic inactivation of the MMR genes, usually methylation of the promoter region of the *MLH1* gene [299,300]. Molecular genetic characteristics of MSI tumors include diploid DNA content and lack of LOH at *APC*, *p53*, and 18q and lower frequencies of *APC* and *p53* mutations [301–303]. Other tumor suppressor genes such as *TGFBRII*, *IGF2R*, and *BAX* may replace *APC* and *p53* function [304–306]. Another molecular alteration found in some MSI-positive tumors is extensive methylation of the CpG islands in the gene promoter regions (see "Methylation" below). Compared with microsatellite-stable colorectal cancers, MSI tumors tend to be in the proximal colon, occur in women, present at an earlier age, have a more favorable prognosis, and histologically are more mucinous, poorly differentiated, and show lymphocytic infiltration [307–309].

Methylation

Methylation is an epigenetic change found in a variety of tumors. Alterations in gene methylation noted in colorectal tumors likely result in significant changes in epithelial cell biology. For example, decreased methylation could allow expression of genes that normally are silent, and conversely increased methylation could lead to silencing of genes that are important for growth suppression. Some colorectal cancers have been described as being CIMP (CpG island methylator phenotype)-positive [310]. CpG islands are aggregates of cytosine–guanine dinucleotide sequences that occur in the promoter regions of genes. Extensive methylation of these cytosine bases results in gene silencing. Cancers with methylation and silencing of multiple genes are termed CIMP positive. Methylation has been implicated in the silencing of the *MLH1* mismatch repair gene and of the *p16* gene in colorectal cancer [311,312]. A variety of other genes have been noted to be methylated, including TMEFF2 (also known as *HPP1* and *TPEF*) and *MGMT* [313,314]. Some investigators have postulated a "serrated" pathway of colorectal carcinogenesis driven by inactivation of DNA repair genes due to promoter methylation. This pathway is distinguished from others by the precursor lesion being a hyperplastic polyp (serrated sessile polyp) rather than an adenoma, and with hyperplastic polyposis as the archetypical phenotype [315].

Other signaling pathways

The TGF-β/SMAD signaling pathway includes TGF-β receptor types I and II (TFG-βRI, TFG-βRII) and SMAD proteins. Binding of TGF-β to TGF-βRII ultimately phosphorylates SMAD2 and results in formation of a complex with SMAD4. This complex then induces synthesis of p15 and p21 leading to growth arrest. Mutations in *SMAD4*, *SMAD2*, and *TGFBR2* have been identified in a minority of colorectal cancers with some alterations at the transition from adenoma to colorectal cancer. Of note, germ-line mutations in *SMAD4* are among the abnormalities responsible for juvenile polyposis, an autosomal dominantly inherited disorder characterized by a high risk of colorectal cancer.

Clinical presentation and diagnosis

Presentation

Patients with colorectal cancer can present with a variety of symptoms (Table 65.7). The most common is abdominal pain (noted in 44% of patients), followed by change in bowel habits (43%), hematochezia or melena (40%), weakness (20%), asymptomatic anemia (11%), and weight loss (6%) [316,317]. Unusual presentations include diverticulitis, fever of unknown origin secondary to abdominal abscesses, enteroentero or enterovesicular fistula formation, *S. bovis* bacteremia, or *Clostridium septicum* sepsis. Also, primary colorectal cancer is the cause of 6% of metastatic adenocarcinomas of unknown origin. About 15% of patients present with acute complications of colorectal cancer including abdominal obstruction, severe abdominal pain, bowel perforation, and massive bleeding necessitating emergent hospitalization. Others can be asymptomatic and diagnosed after work-up of iron deficiency anemia.

Patient symptomatology is dependent on the size, location, and rate of growth of the malignancy. Calculation of the growth rate of a colorectal neoplasm is imprecise, because observation of lesions in the postcolonoscopy era is unacceptable. Nevertheless, several investigators have estimated the polyp dwell time. Portrait studies, which compare mean average patient age for adenoma development with age for cancer diagnosis, calculate this period to be 15–18 years [318]. Direct observation of benign polyp-to-cancer development supports a time frame of 10–15 years [319,320]. Also, polyp dwell times ranging between 18 and 23 years are noted in FAP. Taken together, sporadic colorectal cancer is thought to develop slowly over years. However, in inherited conditions such as HNPCC a significantly accelerated adenoma–carcinoma sequence has been described.

Obstructive symptoms of colicky abdominal pain, abdominal distention, constipation, change in bowel habits, and pain with meals are more often noted in patients with left-sided versus right-sided colonic tumors. These symptoms result from solid feces attempting to pass a narrower left colon lumen compromised by a circumferentially growing tumor. These tumors are sometimes termed "apple-core lesions" after their appearance on radiological studies (Fig. 65.5). By contrast, the cecum and ascending colon are relatively capacious, and liquid feces found in the right colon can traverse areas of significant lumenal compromise without provoking symptoms. Consequently, large right-sided tumors can develop before the patient seeks medical attention.

Rectal bleeding, either gross or occult, is a common symptom of colorectal neoplasia and increases in occurrence and frequency with the size and ulceration of the lesion.

Table 65.7 Common and unusual presentations of colorectal cancer

Common presentations	
Presentation	**Percent affected**
Abdominal pain	44
Change in bowel habits	43
Hematochezia/melena	40
Weakness	20
Asymptomatic anemia	11
Unusual presentations	
Diverticulitis	
Fever of unknown origin (abdominal abscess)	
Fistula (entero-entero, entero-vesicular)	
Septicemia (*Streptococcus bovis*, *Clostridium septicum*)	
Metastatic cancer of unknown origin	

Figure 65.5 Barium enema–air contrast study with hepatic flexure colorectal cancer (bounded by circle) with the classic "apple core" lesion.

Colorectal cancer or adenoma is the second most frequent cause (accounting for 19% of all cases) of overt lower gastrointestinal tract bleeding after diverticular disease [321]. In general, mean rates of bleeding are modest, typically less than 10 mL/day with cecal and ascending tumors and less than 2 mL/day for tumors in other parts of the colorectum [322]. With increased emphasis on colorectal cancer screening, asymptomatic patients with colorectal neoplasia are presenting with occult bleeding found on stool guaiac analysis. Another common presentation is chronic occult blood loss identified by laboratory evidence of iron deficiency anemia (microcytic, hypochromic red blood cell indices and low percent saturation of iron). Bright-red blood per rectum or coating the stool is often a sign of rectal or left colon lesions. By contrast, mahogany-colored stool is a sign of right-sided cancer. Melena, although usually originating from lesions in the upper gastrointestinal (GI) tract, can be caused by cecal tumors with small amounts of bleeding in patients with slow colonic transit. Evaluation of the lower GI tract should be undertaken in patients with no cause of melena found in upper GI tract examination.

In addition to discomfort from intestinal distention, colorectal cancer can generate pain resulting from invasion of tumor into surrounding structures. Acute severe abdominal pain can develop from bowel wall perforation with accompanying peritonitis. Rectal cancer can cause back pain from invasion of tumor into perineal or sacral nerves, tenesmus, pelvic pain from invasion into bladder or vaginal wall, and urinary complaints.

Patients with colorectal cancer can also present with cachexia plus weight loss and loss of appetite and strength. Other constitutional symptoms, including fatigue, shortness of breath, and angina, can occur from anemia secondary to blood loss.

At diagnosis of colorectal cancer, asymptomatic patients have a better 5-year survival rate than symptomatic patients, respectively 71% vs 49% [323,324]. Also, patients presenting with bowel obstruction or bowel perforation have a statistically significantly poorer prognosis than those without these symptoms as adjusted for Dukes stage. Other presenting complaints, including nausea and vomiting, change in bowel habits, and abdominal pain, are not independent prognostic factors [317].

Findings indicative of colorectal cancer can be appreciated on physical exam. On palpation of the abdomen, masses are noted most commonly in the right lower quadrant corresponding to cecal tumors. These lesions can grow to a detectable size secondary to the capacious nature of the cecum. Also, hepatomegaly or liver nodularity could indicate metastatic spread to the liver. Sister Mary Joseph sign (nodular umbilicus from periumbilical lymphadenopathy) can indicate the spread of colon and rectal cancer [325]. Digital rectal exam may reveal masses or gross blood, and stool guiaic analysis may test positive for occult blood. Rarely, jaundice or pulmonary findings from metastatic disease are noted.

The symptoms of colorectal cancer – rectal bleeding, abdominal pain, and change in bowel habits – are occasionally misdiagnosed. Rectal bleeding can be excused as hemorrhoidal disease with deferral of diagnostic evaluation. In fact, failure to diagnose colorectal cancer in those with rectal bleeding is a common cause of action for malpractice suits. In general, patients over the age of 40 with complaints of lower gastrointestinal bleeding should have complete evaluation of the colon. Consideration should be given for a similar workup in younger individuals with a family history of colorectal neoplasia. A change in bowel habits can be dismissed as irritable bowel syndrome (IBS). However, IBS is a diagnosis of exclusion requiring thorough diagnostic workup before this conclusion is reached. This is especially true for atypical patients including males, middle-aged patients with a sudden change in bowel habits, and those without a many-year history of gastrointestinal complaints. Diverticular disease can be confused with the presentation of colorectal cancer, because symptoms and radiological findings can be similar. Consequently, endoscopic evaluation of the colon is recommended after acute diverticulitis, and sooner if the patient is not responding to treatment.

Diagnosis

A variety of tests are available for the assessment of a patient with possible colorectal cancer. The evaluation should begin by obtaining a history, family history (including colorectal and other cancer), physical examination with a digital rectal examination, and laboratory testing with complete blood count (CBC) and comprehensive metabolic panel. Abnormalities in CBC may reflect iron deficiency anemia, electrolyte perturbations may be present, and elevated liver function tests can result from hepatic metastases. Carcinogenic embryonic antigen (CEA) is not useful as a diagnostic or screening test but is drawn preoperatively in colorectal cancer patients to monitor for recurrent tumor postoperatively.

Examination of the colon is best done by colonoscopy (Fig. 65.6). Colonoscopy employs patient sedation and uses a 180-cm endoscope, which can visualize the entire colon 90%–95% of the time. Colonoscopy has superior sensitivity and the ability to perform therapy including polypectomy. In one study, the sensitivity of colonoscopy for polyps measuring 6 mm or greater was 92% [326]. Tandem colonoscopy studies reveal a miss rate for polyps greater than 1 cm of 0%–6% [327,328]. When colonoscopy cannot be performed because of patient factors such as colonic tortuosity or patient infirmity, a double-contrast barium enema – barium enema–air contrast (BAE–AC) – study is an alternative (Fig. 65.5). This procedure involves rectal infusion of both barium contrast and air. In a retrospective study, the sensitivity for colorectal cancer diagnosis for BAE–AC was 85% vs 95% for colonoscopy [329]. In a paired study of BAE–AC and colonoscopy (with colonoscopy as the gold standard), BAE–AC enema identified only 32% of polyps less than 0.5 cm, 53% between

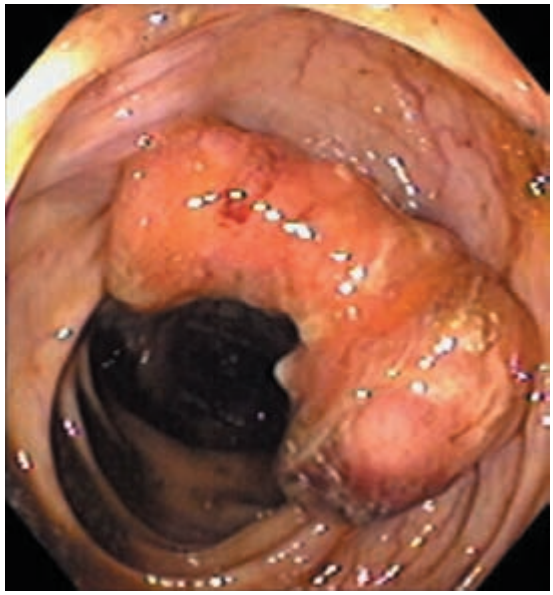

Figure 65.6 Colonoscopy view of colorectal cancer occupying 50% of the circumference of the colon. Courtesy of Dr William Ravich.

0.6 and 1.0 cm, and 48% of polyps greater than 1.0 cm [330]. Single-contrast BAE is a less sensitive technique than BAE–AC and is no longer used for this indication. Barium studies have particular difficulty in visualizing the rectum and sigmoid, so flexible sigmoidoscopy is also required in conjunction for better inspection of these areas. In patients diagnosed with colorectal cancer by radiography or flexible sigmoidoscopy, complete examination with colonoscopy is recommended prior to surgery. This strategy is employed because of the high rate of synchronous (two or more primary) colorectal lesions, which could alter the intended surgical management. Investigators found synchronous cancers in 2.1%–11% [331–334] and synchronous polyps in 24%–28% [333,335] of patients with colorectal cancer. The role of virtual colonoscopy in evaluation of a patient with signs and symptoms of colorectal cancer is unclear, but it may replace barium enema as an alternative to colonoscopy. In one study of virtual colonoscopy in an average-risk screening population, the sensitivity for colorectal polyps measuring 0.6–1.0 cm was equivalent to that of colonoscopy [326]. In patients with colon obstruction obviating complete colonic evaluation preoperatively, colonoscopy should be performed shortly after surgery to evaluate for synchronous tumors.

Preoperative staging

Preoperative cancer staging should be performed on patients with colorectal cancer to enable planning of appropriate management (Table 65.8). History and physical examination with evaluation for metastatic disease is the initial step. Digital rectal examination in patients with rectal cancer helps in planning the appropriate operation by evaluating the distance of the tumor from the dentate line and tumor involvement of the rectal sphincter. Complete visualization of the colon, preferably by colonoscopy, is necessary (see "Diagnosis" above) to exclude synchronous colorectal lesions. Other testing recommended by the National Colorectal Cancer Network and other authors includes CBC, platelet count, and comprehensive metabolic panel including liver and renal function, and carcinoembryonic antigen (CEA) and chest radiography [337,337]. Routine blood testing is relatively insensitive for cancer staging but is important for assessing the patient's ability to receive various treatment options. A high CEA level is a preoperative marker of poor prognosis in patients with stage II disease and can be used to monitor for recurrent cancer postoperatively in those with elevated preoperative levels [338,339]. A chest radiograph is obtained to assess for pulmonary metastasis.

Table 65.8 Preoperative work-up of a colorectal cancer patient

History and physical examination
Digital rectal examination
Complete blood count, platelet count, comprehensive metabolic panel (liver and renal function tests)
Colonoscopy
Carcinoembryonic antigen (CEA)
Chest radiograph
CT scan or MRI scan of the abdomen and pelvis
Rectal endoscopic ultrasound or MRI with endorectal coil (in patients with rectal cancer)

CT, computed tomography; MRI, magnetic resonance imaging.

Imaging the abdomen and pelvis with computed tomography (CT) or magnetic resonance imaging (MRI) to assess for extracolonic malignancy is also recommended. Traditionally CT scanning is used, but MRI is performed in some institutions with local expertise and advanced technology. Scanning by CT has a sensitivity of 81% and a positive predictive value of 100% in detecting Dukes D lesions [340] (Fig. 65.7). Studies show that CT scans provide information used in treatment planning in up to one-third of patients, and definitively alter the mode of treatment in one in six patients [341]. Magnetic resonance imaging appears to have superior specificity for hepatic lesions compared with CT scanning [342]. Positron emission tomography (PET) or PET in combination with CT (PET/CT) is not advocated in preoperative staging because few data regarding the use of this technique in this setting exist to date. Positron emission tomography for malignant disease with fluorine 18-labeled fluoro-2-deoxy-D-glucose (^{18}FDG) is based on the increased glucose demand of malignant cells (Fig. 65.8). The ^{18}FDG is administered intravenously and taken up by malignant cells, which convert the compound to a monophosphate. The monophosphate is trapped in the cell allowing in vivo mapping of the glucose-based tracer. Positron emission tomography is utilized to detect and evaluate the extent of

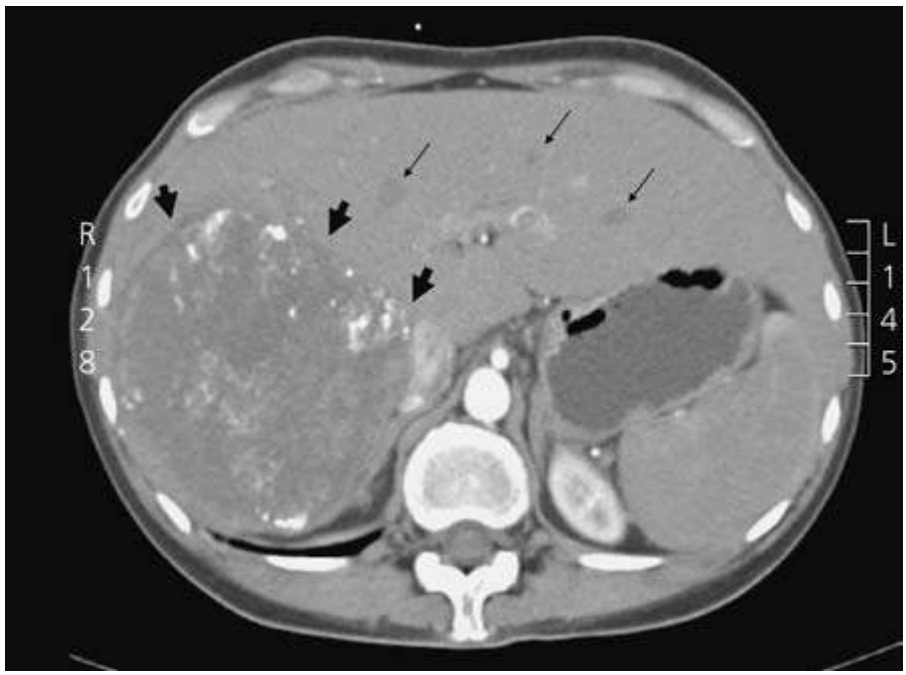

Figure 65.7 Abdominal computed tomography (CT) scan revealing hepatic metastatic lesions from colorectal cancer. Short arrows outline large hepatic metastatic lesion. Long arrows point to smaller additional metastatic lesions.

recurrent disease [343], colorectal liver metastases [344], and undiagnosed metastatic foci in the presence of rising CEA levels [345].

In rectal cancer preoperative determination of level of tumor invasion (T stage) and presence of lymph node involvement (N stage) are of prime importance in management planning.

Courtesy of Dr Christopher Mosley.

Traditionally, rectal endoscopic ultrasound (EUS) has been used for this purpose, but endorectal MRI is increasingly popular. In EUS a rectal endoscopic probe emits ultrasound waves to delineate five layers of the large bowel anatomy, evaluating for depth of tumor invasion and lymph node involvement (Fig. 65.9). Accuracy rates of rectal EUS for the evaluation of the depth of transmural tumor invasion are 82%–88% [346,347], and this technique has been described as superior to others for preoperative staging [348–350]. However, technological advances have meant that the accuracy of thin-section MRI performed with a phased-array coil inserted rectally rivals that of rectal EUS [351,352].

Pathology

Histopathology

Most colorectal cancers are adenocarcinomas arising from the conversion of adenomatous polyps to colorectal carcinoma. Other histological types of large bowel malignancy, including squamous cell cancer at the anorectal junction, cloacogenic cancers, melanoma, lymphoma, and carcinoids, account for less than 3% of colorectal cancers.

Colorectal adenocarcinomas typically form glandular structures (Fig. 65.10). Most have well-differentiated (25%) or moderately well-differentiated (60%) glands. The remainder (15%) are poorly differentiated or undifferentiated [353]. In poorly differentiated cancers, gland formation is less prominent. A histological grading system of differentiation by Compton designates tumors as follows [354]:

- grade1 – well differentiated
- grade 2 – moderately well differentiated

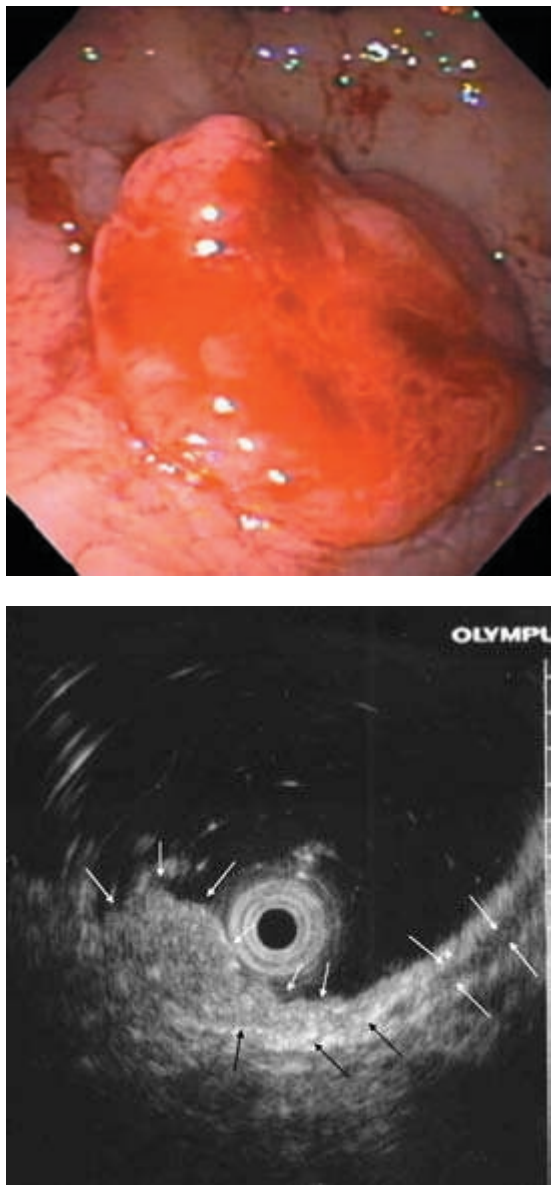

Figure 65.9 Endoscopic ultrasound. **(a)** Endoscopic view of a 3-cm rectal cancer localized 1 cm from anal verge. **(b)** Endoscopic ultrasound of same lesion showing stage II (T3, N0, M0) colorectal cancer. The rectal mass is demarcated by the upper white arrows. Between the white arrows is the dark muscularis propria layer. The rectal cancer invades through the muscularis propria with disruption and loss of this layer as noted by the black arrows. Courtesy of Dr Sergey Kantsevoy.

- grade 3 – poorly differentiated
- grade 4 – undifferentiated.

Several studies have observed that poorer differentiation is a stage-independent factor for poorer prognosis [355,356]. Undifferentiated small cell cancers of the colorectum have been identified as endocrine tumors with a poor prognosis.

Both normal and neoplastic glands secrete mucin, a glycoprotein formed by intestinal goblet cells and identified on routine pathology staining. Most large-bowel cancers secrete little or moderate amounts of mucin. A minimum of 25% of mucin compared with tumor mass is required to describe a cancer as having a mucinous component. Cancers producing abundant mucin (mucin accounts for at least half of the tumor mass) have a grossly gelatinous appearance and are designated as mucinous or colloid (Fig. 65.10). Patients with mucinous tumors tend to be diagnosed at an advanced stage, are less amenable to surgical resection, and have a poorer prognosis than others [357].

Signet-ring cell carcinoma is another rare (0.2%–1%) histological type of colorectal adenocarcinoma. These tumors are identified by signet-ring (i.e., resembling a finger ring bearing an engraved seal) cell morphology with an eccentric crescent-shaped nucleus pushed by intracytoplasmic mucin against the cell wall. Patients with this type of large-bowel cancer have a particularly poor 5-year survival rate compared with others [358].

Gross morphology and spread

Most colorectal cancers develop from colorectal adenomas protruding from the mucosal lining. In Asian populations, particularly the Japanese, investigators have described the frequent development of colorectal adenocarcinomas arising from nonpolypoid or flat lesions, an observation rarely made in Western countries [359].

Colorectal cancers can take several gross pathological forms:

- polypoid – exophytic intralumenal mass without ulceration, more commonly seen in the right colon
- fungating – polypoid cancer with prominent ulceration
- ulcerative – the surface of the lesion on a level with or ulcerating below the normal mucosa, more often found in the left and sigmoid colon
- infiltrative – infiltration of the intestinal wall, often circumferentially forming a constricting mass.

At the time of diagnosis multiple primary cancers (synchronous cancers) can be found in 3%–6% of patients with presumed sporadic colorectal cancer, and in 18% and 21% of patients with ulcerative colitis and FAP, respectively [360,361].

Colorectal cancer usually arises as a small focus of neoplastic cells in an adenoma. With time the malignancy invades perpendicularly to the intestinal lumen through various layers of the large bowel, and penetrates the bowel wall to involve neighboring organs and the peritoneal cavity. Once the tumor penetrates the muscularis mucosae layer of the intestine, it can access the lymphatic and vascular system and spread to regional and extraregional lymph nodes, hence forming distant metastases. The liver is the most common site of metastasis because venous drainage from the large bowel is directed through the portal circulation. Pulmonary metastases occur especially in tumors of the lower third of rectum, which is also drained by veins emptying into the inferior vena cava. Rectal cancer is characterized by involvement of local structures because of the lack of a serosal lining and

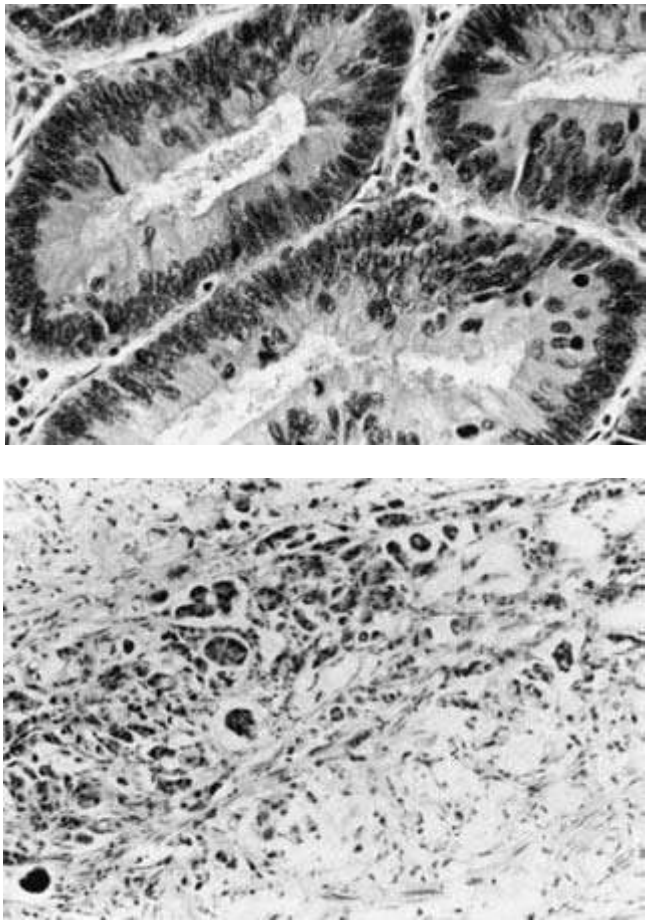

Figure 65.10 **(a)** Well-differentiated adenocarcinoma of the colon with characteristic gland-like formation. In each gland, the nuclei are large, the chromatin is poorly condensed, the nuclei are stratified away from the basement membrane, and mitoses are common. **(b)** Mucinous or colorectal cancer with cancer cell suspended in pools of mucin (dark nuclei) and typical glands are not seen.

close confinement in the pelvis. Also, vertebral metastasis can occur through communication of the portal and vertebral venous circulation through the Batson plexus.

Staging

An understanding of intestinal histology is crucial for accurate pathological staging of colorectal cancer. The large bowel is organized into four layers: mucosa, submucosa, muscularis propria, and serosa (Fig. 65.11). The innermost layer, the mucosa, has three parts: the epithelium, which lines the intestinal lumen; the lamina propria, containing connective and smooth muscle fibers; and the muscularis mucosae, a thin double layer of smooth muscle separating the mucosa from the submucosa. The submucosa contains lymphatics, blood vessels, and nerve fibers. The muscularis propria is composed of an inner circular smooth muscle and an outer layer of longitudinal muscle. The serosa is formed of mesenchymal elements and is lined externally by a single layer of mesothelial cells. Importantly, colorectal malignancy is defined by aberrant mucosal cells penetrating the muscularis mucosae and escaping confinement by gaining access to submucosal lymphatic and vascular channels.

The first system of colorectal cancer staging was devised in 1932 by Cuthbert Esquire Dukes, a Scottish pathologist who proposed a method of rectal cancer classification based on surgical resection specimens [362]. Dukes divided staging into three stages:

- stage A – tumor restricted to but not through the bowel wall
- stage B – tumor through the bowel wall
- stage C – tumor spread to lymph nodes.

Stage D to denote metastatic disease was added later. The Dukes classification has been adapted several times producing, among others, the Astler–Coller and the Dukes–Turnbull classifications. The Dukes–Turnbull is perhaps the most commonly used system and is diagrammed and explained in Fig. 65.11.

Today, colorectal cancer is classified using the TNM (tumor, node, metastasis) scheme discussed below. However, familiarity with Dukes classifications is still relevant because these systems stubbornly persist in clinical practice and understanding of them is necessary to interpret historical therapeutic trials.

TNM staging

To provide a more uniform pathological classification, the American Joint Committee on Cancer (AJCC) and the Union Internationale Contre Le Cancer (UICC) developed a system based on evaluation of the extent of the primary tumor (T), extent of local and regional lymph node involvement (N), and presence or absence of metastatic disease (M) [363]. TNM staging has replaced the Dukes classifications and is summarized as follows:

T stage

- T0 – no evidence of primary tumor
- Tis – in situ adenocarcinoma (high-grade dysplasia, carcinoma in situ); tumor confined to the mucosa and not breaching the muscularis mucosae
- T1 – tumor invades the submucosa but not the muscularis propria
- T2 – tumor invades into but not through the muscularis propria
- T3 – cancer invades through the muscularis propria into subserosa or nonperitonealized extramural tissues
- T4 – cancer directly invades other organs or structures (T4a) or perforates visceral peritoneum (T4b).

N stage

- Nx – lymph nodes cannot be assessed
- N0 – no lymph node involvement

Stage		Depth of invasion	Frequency among invasive cancers	Observed 3-year survival	Actuarial cancer-free 5-year survival
Carcinoma in situ		Noninvasive			100%
A(I)		Penetrates the muscularis mucosae; invades the submucosa but does not penetrate the muscularis propria	15%	83%	95%–100%
B(II)		Penetrates muscularis propria and may extend through the serosa into pericolic fat (B1 into the muscularis propria; B2 through the serosa)	31%	79%	80%–85%
C(III)		Any invasion, plus regional lymph node metastases (C1 = ≤ 4; C2 = > 4)	23%	56%	50%–70%
D(IV)		Distant metastases	30%	5%	5%–15%

Figure 65.11 Dukes–Turnbull classification A through D with TNM stage in parentheses. The 3-year survival and actuarial cancer-free 5-year survivals for each stage are shown.

- N1 – metastasis in one to three regional lymph nodes
- N2 – metastasis in four or more regional lymph nodes.

Note: prognosis correlates with the number of lymph nodes inspected in the pathological resection specimen. Consequently the AJCC/UICC mandates that a minimum of seven lymph nodes should be inspected.

M stage

- MX – distant metastasis cannot be assessed
- M0 – no distant metastasis
- M1 – presence of distant metastasis.

Involvement of nonregional lymph nodes including common iliac, external iliac, paraaortic, and supraclavicular, is considered distant metastasis.

R stage

This refers to residual tumor at the margins of resected specimens and is designated as follows:

- R0 – complete surgical resection without microscopic evidence of tumor
- R1 – complete resection with microscopically positive margins for tumor
- R2 – incomplete surgical resection with grossly positive margins for tumor.

Patients with a more advanced R stage have poorer prognosis and are considered ineligible for adjuvant chemotherapy.

The AJCC/UICC system has eight stages (stage 0, I, IIA, IIB, IIIA, IIIB, IIIC, IV). Table 65.9 gives the 5-year survival rates for colon cancer when patients are staged according to this scheme [364]. Table 65.10 compares the original Dukes stages and the Astler–Coller modification of Dukes stages with the TNM stages.

Table 65.10 Dukes staging and Dukes modified Astler–Coller staging compared with TNM stages

Dukes stage	TNM stages
A	T1 or T2, N0, M0
B	T3 or T4, N0, M0

Treatment

Surgery

Principles

Surgery is the treatment of choice for most patients with colorectal cancer. Surgical resection provides the best chance for long-term cure of the primary tumor, isolated recurrence at the colorectal anastomotic site, and metastatic lesions in the liver and lung. The basic surgical approach is an anatomical en bloc resection of the primary tumor with adequate margins and removal of the regional lymph nodes. This strategy stems from the finding that pericolic mesenteric lymph nodes are the initial site of metastatic spread, and node status carries diagnostic and therapeutic significance. The blood supply and lymph node chains follow parallel courses facilitating en bloc resection. Colorectal resection should include the tumor and 5-cm margins on either side of the cancer. When colorectal cancer has invaded or attached to other organs, en bloc resection including these organs is necessary to achieve a curative resection [365]. Previously, a no-touch surgical technique of tumor isolation and resection was encouraged to prevent detachment and circulation of tumor cells. However, subsequent evidence suggests that this technique is not justified because of the absence of escaping tumor cells in the circulation [366].

The surgical approach for stage I, II, and III colorectal cancer is based on the size and location of the tumor.

Table 65.9 Staging system recommended by the American Joint Commission on Cancer and the Union Internationale Contre Le Cancer, and corresponding 5-year survival rates

Stages	T (primary tumor)	N (lymph nodes)	M (metastatic disease)	5-year survival (%)
0	Tis	N0	M0	
I	T1–T2	N0	M0	93.2
IIA	T3	N0	M0	84.7
IIB	T4	N0	M0	74.2
IIIA	T1–T2	N1	M0	83.4
IIIB	T3–T4	N1	M0	64.1
IIIC	Any T	N2	M0	44.3
IV	Any T	Any N	M1	8.1

Adenocarcinoma is encountered in the cecum and ascending colon 15% of the time, in the transverse colon in 8% of cases, and in the splenic flexure and descending colon on 5% of occasions. The majority of sporadic cancer is found in the sigmoid and rectum.

Colonic cancers

Cecum and ascending colon

Cancers in the right colon require a right hemicolectomy (Fig. 65.12a). This procedure involves resection of the intestine from several centimeters proximal to the ileocecal value to one-third of the distance along the transverse colon.

Transverse colon

Proximal transverse lesions near the hepatic flexure are treated with an extended right hemicolectomy. Intestine is removed from several centimeters proximal to the ileocecal valve to the middle of the transverse colon. Distal transverse colon lesions are resected with an extended left hemicolectomy.

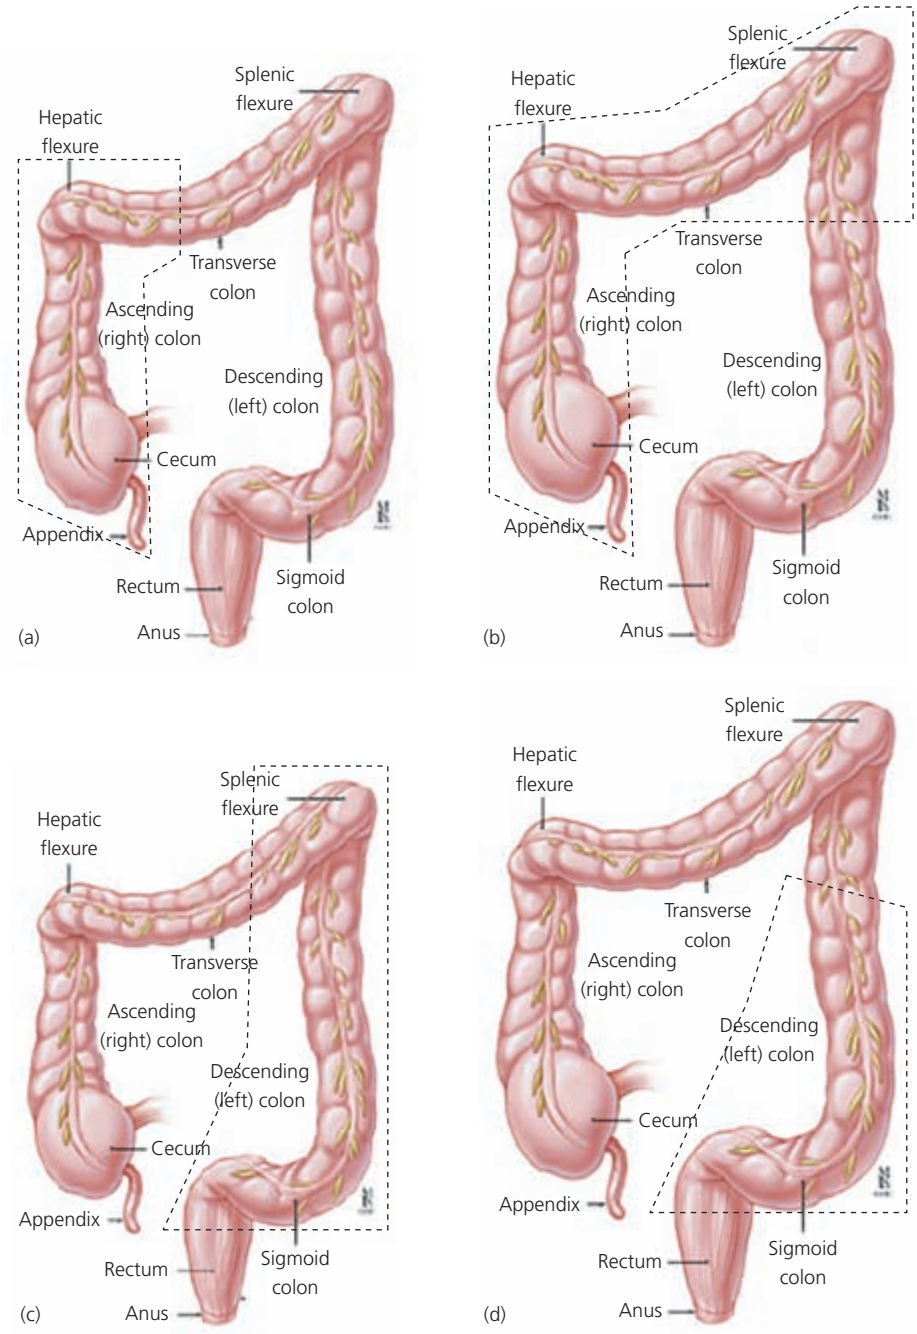

Figure 65.12 Types of surgical resection of colorectal neoplasia. **(a)** Right hemicolectomy. **(b)** Extended right hemicolectomy. **(c)** Left hemicolectomy. **(d)** Sigmoid resection. Adapted from the Johns Hopkins Gastroenterology and Hepatology Resource Center (http://hopkinsgi.org), with permission.

Mid-transverse lesions involve resection of the colon from several centimeters proximal to the ileocecal valve to approximately one-third the way along the descending colon (Fig. 65.12b).

Descending and sigmoid colon

For lesions in the proximal half of the descending colon a left hemicolectomy is performed (Fig. 65.12c). This involves removal of the colon from halfway along the transverse colon to the region of the sigmoid colon. For tumors in the sigmoid colon, data suggest that a more limited operation, a sigmoid colectomy, has comparable survival and less morbidity and mortality than left hemicolectomy [367] (Fig. 65.12d). A sigmoid colectomy involves the removal of bowel from halfway down the descending colon to the peritoneal reflection in the rectum.

Total abdominal proctocolectomy

This procedure involves removal of the entire colon and rectum with ileostomy or construction of a continent pouch from terminal ileum. This operation is indicated for those with FAP and ulcerative colitis. Several studies reveal little difference in functional outcome, particularly bowel frequency, between ileorectal anastomosis and restorative proctocolectomy with an ileal pouch [368,369].

Total abdominal colectomy

Total abdominal colectomy involves removal of the colon with preservation of the rectum and ileorectal anastomosis. This operative procedure is indicated for patients with a high risk of colorectal cancer including those with AFAP or HNPCC, and some with FAP. Postoperative endoscopic surveillance of the retained rectum for metachronous adenomas and cancers every 6–12 months is mandatory.

Rectal cancer

The management of stage II and III rectal cancer usually involves three modalities of treatment – surgery, chemotherapy, and radiation. The surgical approach to rectal cancer depends on tumor stage and location within the rectum. Most patients with stage I, II, and III rectal cancers undergo rectal excision, although some stage I patients are treated with more limited transanal resection. The rectum can be divided into three parts:

- the lower rectum – from the dentate line to the left lower valve of Houston (approximately 0–7 cm from the anal verge)
- the middle rectum – from the left lower valve of Houston to the peritoneal reflection or right middle valve of Houston (approximately 7–11 cm from the anal verge)
- the upper rectum – from the peritoneal reflection to the left upper valve of Houston (approximately 11–15 cm from the anal verge).

For stage I rectal cancers (T1 or T2, N0), some surgeons have utilized transanal excision rather than radical rectal excision for rectal tumors that invade into but not through the submucosa (T1) or invade into but not through the muscularis propria (T2) in the absence of lymph node involvement (N0). This procedure removes rectal tumors with surrounding mucosa through the anus, sparing the patient the morbidity of an extensive rectal resection. Patients typically selected for this procedure include those with tumors within 8–10 cm of the anal verge, in which the tumor encompasses less than 40% of the circumference of the bowel, with well-differentiated histology, and no lymph or blood vessel involvement. However, despite stringent selection criteria, the local recurrence rates of tumor after local excision can be as high as 18% for T1 and 37% for T2 tumors [370,371]. Consequently, the role of local excision as a curative procedure remains controversial [372].

Upper rectal cancers

The upper third of the rectum is intraperitoneal. The usual surgical approach in this location is to perform a low anterior resection (LAR), which preserves the internal and external rectal sphincters and creates an end-to-end anastomosis to restore intestinal continuity. This operation is usually performed through an anterior incision.

Middle rectal cancers

The middle rectum transitions between an intraperitoneal and extraperitoneal structure. Tumors in this area are usually removed by a LAR. At the time of the LAR a temporary ileostomy or colostomy is created to allow for wound healing of the low anastomosis.

Distal rectal cancers

Most patients with distal rectal tumors have abdominal peritoneal resections (APR). This operation involves removal of the rectosigmoid, rectum, and anus by a combined abdominal and peritoneal approach and leaves most patients with a permanent colostomy. Such a procedure is necessary because surgical margins of 2 cm from the tumor are required for a curative operation. Margins greater than 2 cm appear unnecessary because less than 6% of tumors demonstrate intramural spread beyond 2 cm; the majority of patients with tumor invasion beyond 2 cm have advanced stage disease, and distant metastases are the life-limiting issue, not local recurrence [373]. In some patients in whom at least 2 cm of distal margin can be resected, intestinal continuity can be restored by a coloanal anastomosis suturing the distal colon to the anus. Some surgeons make an anal colonic pouch prior to anastomosis to the anus. Also, in some cases preoperative chemoradiation may downsize the tumor allowing for less radical surgical approaches.

Total mesorectal excision

The mesorectum is a structure surrounding the rectum that contains the blood supply and the lymphatics for the upper,

middle, and lower rectum. Microscopic spread of tumor to the mesorectum is noted in almost 40% of patients undergoing surgery for rectal cancer [374]. Conventional rectal excision involving blunt technique along indefinable tissue planes has been supplanted by total mesorectal excision (TME). In this surgical technique, under direct visualization, sharp dissection along definable planes is done of the mesorectum posteriorly and laterally down to the pelvic floor and midline anococcygeal raphe. This technique accomplishes complete resection of an intact package of the rectum and surrounding mesorectum, enveloped within the visceral pelvic fascia with uninvolved circumferential margins. Multiple studies report that this procedure decreases local recurrence and increases overall survival. With TME, 5-year survival figures have risen from 45%–50% to 75%, local recurrence rates have declined from 30% to 5%–8%, sphincter preservation has risen by at least 20% for mid- and lower rectal cancers, and the rates of impotence and bladder dysfunction have declined from 50%–85% to 15% or less [375]. Consequently, TME has become the standard for surgery of lower and middle rectal cancer.

Laparoscopic colonic resection

Unlike the rapid acceptance and use of laparoscopic cholecystectomy, few colorectal surgeons practice laparoscopic colonic resection, although both techniques were introduced into surgical practice at about the same time [376]. Reluctance to adapt this procedure comes from initial concerns of inadequacy of resection margins, inadequate node sampling, and seeding of port sites. However, four randomized studies of laparoscopic versus open laparotomy revealed comparable numbers of lymph nodes retrieved, adequate surgical resection margins in both groups [377–380], and port site recurrence in one study [379]. No difference in disease-specific survival was noted between groups in the two large studies [379,380], and a third smaller study demonstrated a difference in favor of the laparoscopic group [378]. Patients undergoing laparoscopic procedures have less pain, a lower requirement for postoperative narcotics, reduced ileus [377,381], and possibly less postoperative morbidity than patients having open procedures [377,378,382]. Barriers to further acceptance of this procedure include a steep learning curve and increased operative time for laparoscopic colectomy.

Palliative surgery

Surgical management for stage IV colorectal cancer by resection of the primary tumor or diversion for symptoms of obstruction or bleeding is almost always indicated and provides significant palliation. In patients with intraperitoneal disease with obstruction, palliation can be done with surgical bypass or ostomy. Recurrence at the site of prior anastomosis can potentially be cured. In patients with multiple medical problems or at high surgical risk, palliation with fulguration of the rectal tumors using snare polypectomy or laser ablation is possible.

Liver metastasis

Liver metastasis from colorectal cancer is a common occurrence, with 50 000 Americans presenting annually with this condition [383]. After resection of the primary tumor, the liver is the most frequent site of relapse (33%) of colorectal cancer [384]. Approximately 70%–80% of hepatic metastases appear within 2 years of primary tumor resection. Nearly half of all patients dying with colorectal cancer will have liver-limited disease at autopsy. Surgical resection is the best treatment for long-term outcome, but only a minority (about 25%) of patients have resectable metastatic liver disease. The major reasons for unresectability include the number of lesions, proximity to major vascular structures, and preexisting liver disease. Of those undergoing curative resection, the 5-year survival rate is about 25%–35% [383,385]. The mortality of hepatic resection ranges from 1% to 4%, and the morbidity is 8%–12% [386], but without aggressive intervention the average survival of patients with liver metastases is 8 months [387,388]. Traditional criteria for liver resection include patients with three or fewer metastatic lesions in one lobe of the liver, lesions less than 5 cm in size, the ability to leave margins of greater than 1 cm, and the absence of extrahepatic disease. Over time surgeons have liberalized eligibility for surgery. It is noteworthy that patients who have undergone previous hepatic resection benefit from repeat resection if possible, with the 5-year survival in these individuals as high as 41% [387]. Intraoperative ultrasound is necessary to increase the ability to detect metastatic lesions deep within the liver and to identify and avoid vascular structures.

Hepatic lesions not amenable to surgical resection are often treated with ablative therapies. These include intraarterial chemoembolization, injection of ethanol, cryotherapy, and radiofrequency ablation. The latter two are most commonly used for patients with colorectal cancer metastasis. Cryotherapy employs rapid freezing of tissue causing crystal formation and cell death. Radiofrequency ablation uses heat to cause tumor necrosis. Both techniques are done under ultrasound guidance at the time of surgery, and radiofrequency ablation can be accomplished percutaneously. The effectiveness of these ablative therapies is difficult to evaluate because they are often performed in combination with other treatment modalities. A summary of radiofrequency ablation reported a 2%–39% recurrence of tumor at the ablated site [389].

Another treatment modality for unresectable liver metastases is hepatic arterial infusion (HAI). A pump containing a chemotherapeutic agent is surgically placed subcutaneously and an attached catheter is implanted into the hepatic artery to deliver the agent directly into the liver. In HAI, agents taken up by the liver by the first-pass effect deliver a significant

concentration of drug to the tumor while minimizing systemic toxicity. A number of randomized trials evaluating the use of HAI chemotherapy versus systemic chemotherapy have demonstrated a significant advantage in terms of response rate and progression-free survival for HAI. However, the overall advantage is small. For example, a study of HAI therapy versus systemic 5-fluorouracil (5-FU) and leucovorin in 135 patients with unresectable liver metastases showed survival of 24.9 months with HAI and 20.0 months with systemic chemotherapy, and response rates of 47% and 24%, respectively [390]. Subsequent studies utilizing HAI and systemic chemotherapy in patients with unresectable liver disease have produced response rates of greater than 70% [391,392]. Also, adjuvant therapy with HAI and systemic chemotherapy may be useful after liver resection [393].

Postoperative surveillance

The 5-year survival rate after surgical resection of the primary tumor is 90% for those with localized disease but drops to 65% in individuals with metastases in regional lymph nodes [394]. The most frequent sites of relapse after surgery are the liver (33%), lungs (22%), locoregional sites (21%), and intraabdominal sites (18%) [384]. Rectal cancers, when compared with colonic cancers, have proportionally more local recurrences and less involving retroperitoneal nodes [384]. The median time to recurrence for patients is 16.7 months, and the majority of recurrences occur within 3 years.

After surgical resection of colorectal cancer, the standard of care is surveillance to improve survival through earlier detection of cancer recurrence and metachronous colorectal neoplasia (Table 65.11). The effectiveness of various strategies of surveillance is difficult to evaluate, because different publications utilize different outcome variables and surveillance protocols. However, three independent metaanalyses of randomized studies all noted a reduction in death from all causes with more intensive follow-up, with a decrease in relative risk and absolute risk of 20% and 7%, respectively [395–397].

Evidence-based colorectal cancer surveillance guidelines have been published by the American Society of Clinical Oncology (ASCO) [398] and the National Comprehensive Cancer Network (NCCN) [399,400]. Both groups recommend periodic postoperative history-taking and physical examination, CEA testing, and colonoscopy, but differ on the frequency of these examinations. These groups do not advocate regular fecal occult blood, CBC, liver function testing, chest radiography, MRI, CT, or ultrasound scans of the abdomen or pelvis in the absence of clinical signs or symptoms [401].

Adjuvant chemotherapy

After years of minimal progress, six new chemotherapeutic agents for the treatment of colorectal cancer have been introduced since the mid-1990s [402]. The evolving use and indications for these agents necessitates that health-care providers continually review the primary medical literature for the latest strategies of therapy.

The primary treatment of stage II and III colorectal cancer is surgical resection. Despite removal of the primary tumor and accompanying lymph nodes in these patients with cancer invading the serosa or lymph nodes, high recurrence rates are noted. Of all patients resectable for cure at presentation, about 37% will fail primary therapy with recurrence of

Table 65.11 Surveillance guidelines after primary surgery with curative intent

Test or procedure	NCCN[a]	ASCO[b]
History and physical examination	Every 3 months for 2 years, then every 6 months for 3 years; counseling for family history	Every 3–6 months for the first 3 years, annually thereafter
Carcinoembryonic antigen test	Every 3 months for 2 years, then every 6 months for 3 years for T2 or higher-grade lesions if patient is a potential candidate for aggressive curative surgery	If resection of liver metastases is clinically indicated, postoperative testing may be performed every 2–3 months in patients with stage II or stage III disease for 2 years or longer after diagnosis
Flexible sigmoidoscopy and endoscopic ultrasound	Not addressed	For patients who have not received pelvic irradiation, direct imaging of the rectum at periodic intervals is suggested For patients who have received pelvic irradiation, direct imaging of the rectum (except colonoscopy at 3–5 years) is not suggested
Colonoscopy and barium enema	Colonoscopy 1 year after primary therapy; repeat in 1 year if abnormal or every 3 years if negative for polyps If no preoperative colonoscopy is performed because of obstructing lesion, perform colonoscopy in 3–6 months	Colonoscopy postoperatively if not yet done; if high-risk polyps present, excise and repeat colonoscopy annually as long as polyps found; if low-risk polyps, repeat colonoscopy in 3–5 years

tumor [403]. The cause of recurrence is likely residual microscopic tumor foci not removed by initial surgery. The role of adjuvant chemotherapy is to eradicate postoperative residual microscopic cancer in those without known metastatic disease. Adjuvant treatment is most effective if given soon after surgery (within 8 weeks) when tumor burden is minimal. Adjuvant chemotherapy is advocated for patients with stage III colon cancer, and is controversial for those with stage II. In the United States and Western Europe about 29% of all patients have stage III disease (about 90 000 annually) and 26% have stage II.

Colon cancer

For almost the past half century, chemotherapy of colorectal cancer has centered on the use of 5-fluorouracil (5-FU) [404]. Patented in 1957, this agent requires intracellular activation to exert its antitumor activity. It kills cancer cells by disrupting DNA and protein synthesis through inhibition of thymidylate synthetase and the incorporation of metabolites as false nucleotides into DNA and RNA. This drug was utilized in the first large trial to show benefit of adjuvant chemotherapy for colorectal cancer in 1988 [405]. This study randomized 1166 Dukes B and C colorectal cancer patients to curative surgery followed by either no treatment; chemotherapy with 5-FU, semustine, and vincristine; or bacille Calmette–Guérin (BCG). Results revealed an overall improvement in disease-free survival ($P = 0.02$) and survival ($P = 0.05$) in favor of the chemotherapy-treated group.

In 1990, positive results of adjuvant chemotherapy were published in a smaller [406] and then a larger study (INT 0035) of 5-FU with levamisole [407]. Levamisole is an anthelmintic drug used by veterinarians to deworm cattle and sheep, and thought to have anticancer activity due to its enhancement of the immune response. The INT 0035 trial included 1293 patients with either locally invasive (stage B2) or with regional node (stage C) involvement. These individuals were randomized to either observation or a 1-year course of 5-FU combined with levamisole. Stage C patients could also be randomized to levamisole alone. At a median follow-up of 3 years, stage C patients treated with 5-FU and levamisole had their risk of cancer recurrence reduced by 41% ($P < 0.001$) and of death by 33% ($P = 0.006$). Treatment with levamisole alone had no detectable effect. The results in stage B2 patients were equivocal. Subsequently, longer-term follow-up with a median of 6.5 years confirmed these results [408]. This 1990 study prompted a consensus statement from the NCI establishing adjuvant chemotherapy as the standard of care for colorectal cancer patients with stage C disease [409].

The efficacy of the combination of 5-FU with leucovorin (folinic acid), a biomodulator that accentuates the cytotoxic effect of 5-FU, was first noted in the treatment of metastatic colorectal cancer. Consequently, this combination was used as adjuvant therapy in stage II and III colorectal cancer in two small studies and one medium-sized study, all with virtually identical protocols. Pooled analysis from these trials of 1493 patients randomized to either 6-month chemotherapy or observation revealed a statistically significant reduction of mortality and increased 3-year event-free survival in those receiving chemotherapy [410]. Subsequently, evaluation of 5-FU and leucovorin revealed a slight but statistically significant advantage of this regimen compared with 5-FU and levamisole in 5-year disease-free survival. Also, levamisole added to 5-FU and leucovorin provided no advantage [411]. Consequently, 6 months of treatment with 5-FU and leucovorin became the new standard of care for stage III disease adjuvant chemotherapy at the end of the 20th century [412–414].

Investigators have attempted to improve standard adjuvant treatment with 5-FU and leucovorin (Table 65.12). Oxaliplatin improves the efficacy of this combination in those with metastatic colorectal cancer. In an evaluation of adding oxaliplatin to standard adjuvant treatment, a total of

Table 65.12 Results of adjuvant chemotherapy for stage II and stage III colon cancer

Treatment	Ref.	Stage	3-year disease-free survival (%)	5-year disease-free survival (%)	5-year survival (%)
Observation	[419]	II	79	73	80
	[408]	III	52	45	54

	[411]	III		57	67
5-FU and leucovorin	[415]	II	85		
	[415]	III	66		
5-FU, leucovorin, and oxaliplatin	[415]	II	88		
	[415]	III	73		

5-FU, 5-fluorouracil.

2246 patients who had undergone curative resection for stage II or III colon cancer were randomized to receive 5-FU and leucovorin alone or with oxaliplatin for 6 months [415]. The results of this trial revealed an improvement in the standard adjuvant treatment with the addition of oxaliplatin, with disease-free survival at 3 years of 78.2% in the triple drug arm compared with 72.9% with standard adjuvant treatment ($P = 0.002$). In this study no significant interaction between the stage of disease and the treatment was noted, indicating that 5-FU and leucovorin plus oxaliplatin benefited both stage II and stage III colorectal cancer patients, although no statistically significant improvement in outcome was noted in stage II patients. However, the use of oxaliplatin adds significant sensory neuropathy to the adjuvant regimen. Although the incidence of serious grade 3 sensory neuropathy declined from 12.4% during treatment to 1.1% at 1 year of follow-up in this study, long-lasting adverse effects with grade 1 neuropathy were reported in 19% of patients at 18 months of follow-up.

Compared with intravenous 5-FU, oral 5-FU prodrugs such as capecitabine and tegafur–uracil appear to have comparable efficacy and favorable toxicity in some 5-FU and leucovorin regimens [416,417]. Other combinations being studied and contemplated are use of standard adjuvant therapy with irinotecan, and the monoclonal antibody-based agents cetuximab and bevacizumab.

Adjuvant chemotherapy for patients with stage III colorectal cancer is the standard of care. However, whether adjuvant therapy is appropriate for stage II patients is controversial. The debate was initially generated by opposite conclusions of two large groups of investigators. The National Surgical Adjuvant Breast and Bowel Project [418] reported benefits for stage II and III patients, whereas the International Multicentre Pooled Analysis of B2 Colon Cancer Trials (IMPACT B2) [419] found no statistically significant advantage in treating stage II patients. However, a pooled analysis of 3300 patients from five randomized trials [420] concluded that stage II individuals had a small but statistically significant benefit from surgery followed by adjuvant 5-FU-based chemotherapy compared with surgery alone (5-year disease-free survival 76% vs 72%, respectively), and that stage III patients had greater benefit. This study did not factor in the analysis a host of prognostic factors in stage II patients including colonic obstruction, total lymph nodes examined, or preoperative CEA levels. Treatment of stage II patients with adjuvant chemotherapy remains controversial, and decisions are made by physicians and patients, balancing risk and benefit on a case-by-case basis. A model assessing individual patient 5-year disease-free survival and overall survival [420] is available for physicians on the Mayo Clinic website (http://www.mayoclinic.com/calcs). In practice, adjuvant treatment is being administered to a significant proportion (27%) of stage II patients as reported in a Medicare population-based survey [421].

Rectal cancer

The anatomy of the rectum, confined between bony structures of the pelvis, makes surgical excision of rectal cancer difficult. Even with optimal operative technique employing total mesorectal excision, up to 15% of patients with tumors that infiltrate into the perirectal fat or spread to local lymph nodes develop local recurrence [422]. In addition to limitation of overall survival, local recurrence can lead to pelvic pain and urological disturbances.

To improve local recurrence rates, radiotherapy with or without chemotherapy before or after surgery has been employed. Studies reveal that rectal surgery followed by chemoradiation decreases local recurrence rate and improves overall survival in patients with stage II and stage III rectal cancer compared with surgery alone or surgery and radiotherapy [423,424]. Consequently, a 1990 National Institutes of Health consensus statement recommended postoperative adjuvant chemoradiotherapy as standard treatment for patients with rectal cancer classified as TNM stage II (tumor penetrating the rectal wall, without regional lymph node involvement) or stage III (any tumor with regional lymph node involvement) [425]. Subsequent trials have attempted to define the optimal timing of chemoradiation. A metaanalysis concluded that the combination of preoperative radiotherapy and surgery compared with surgery alone significantly improved local control and overall survival [426]. Subsequently, prospective evaluation of preoperative adjuvant treatment (neoadjuvant treatment) versus postoperative chemoradiation was reported [427]. Preoperative treatment with radiation and 5-FU did not improve overall survival but was associated with reduced toxicity and improved local control (6% vs 13% recurrence rate, respectively) compared with postoperative adjuvant treatment. The main disadvantage of the preoperative approach is that optimal selection of patients most likely to benefit from adjuvant treatment is impossible, because there is no resection specimen from which to assess the initial cancer stage; hence, some patients may be unnecessarily treated. However, surgeons favor preoperative treatment for several reasons: it avoids radiation toxicity to loops of small intestine postoperatively fixed to the pelvis; it can occasionally downstage the tumor prior to surgery allowing sphincter-saving procedures; and it avoids damage and complication to the reconstructed neorectum. Consequently, emphasis is shifting in the practice community toward preoperative (neoadjuvant) rather than postoperative adjuvant treatment. Adjuvant chemotherapy with 5-FU and 5-FU with leucovorin is superior or equivalent to other regimens tried.

Metastatic disease

About 22% of patients presenting with colorectal cancer have stage IV disease, defined as those with distant metastases regardless of depth of tumor invasion into the bowel wall or lymph node status. The 5-year survival rate for

stage IV disease is 5%–7% [428]. Patients with unresectable metastatic disease have incurable cancer, and subsequent treatment must be viewed as palliative care. The potential benefits of chemotherapy – including control of symptoms, lengthening of progression-free and overall survival – must be balanced against the risks of these toxic agents on a case-by-case basis. To date, the value of chemotherapy in this setting is disappointing; metaanalysis of systemic chemotherapy trials in patients with metastatic colorectal cancer reveals an improvement in 1-year survival from 34% to 50%, and an improvement in median survival of 3.7 months [429].

The cornerstone of treatment of patients with stage IV colorectal cancer is 5-FU, which remains central to all effective chemotherapeutic regimens in metastatic colorectal cancer. Given as a single agent, 5-FU has superior efficacy compared with a multitude of other agents evaluated. Combination with leucovorin enhances 5-FU efficacy by stabilizing the binding of fluorouracil to thymidylate synthetase [430]. For many years this combination was the standard of care for metastatic disease treatment, with prospective studies revealing reduced tumor size in 20% of patients and prolongation of median survival, from 5 months without chemotherapy to 11–12 months with chemotherapy [431–433]. Addition of other agents to 5-FU such as methotrexate or interferon failed to showed superiority to 5-FU and leucovorin [432–434]. Several trials to determine the optimal dosing, administration, and schedule of 5-FU and leucovorin have been conducted. Infusional administration of 5-FU has less toxicity than bolus administration, with equivalent efficacy. Capecitabine (Xeloda), an oral precursor of 5-FU, appears to have favorable safety and efficacy compared with some parenterally administered 5-FU regimens and is under study as an alternative dosing method for use in combination regimens.

After 30 years of little progress, the past decade has seen the introduction of several new drugs for the treatment of colorectal cancer (Table 65.13). Irinotecan (Camptosar, CPT-11), an analogue of camptothecin approved in 1996, is a chemotherapeutic agent that inhibits topoisomerase I activity leading to DNA fragmentation and cell death [435]. Addition of irinotecan to 5-FU and leucovorin chemotherapy significantly improves tumor response rate (13%–18%), and increases time to progression (median of 2.3–2.7 months) and survival (median of 2.2–3.3 months) [436,437]. The commonly used regimen developed in France, called FOLFIRI, consists of leucovorin (known also as folinic acid [FOL]), 5-FU (F), and irinotecan (IRI), with 5-FU given as an infusion and the other drugs given as bolus therapy [438]. Oxaliplatin (Eloxatin), approved for use in 2002, is a platinum analogue that exerts chemotherapeutic effect by the formation of platinum–DNA adducts that block DNA replication and transcription; it also possibly interferes with RNA synthesis [439]. The combination of oxaliplatin with 5-FU and leucovorin, with 5-FU infused over 46 h – (FOLFOX) = leucovorin (or folinic acid, FOL), 5-FU (F), and oxaliplatin (OX) – provides superior response rates and times to disease progression compared with 5-FU and leucovorin alone [440–442]. Most evaluations of irinotecan, 5-FU, and leucovorin compared with regimens based on oxaliplatin, 5-FU, and leucovorin suggest equivalence between these treatments [443,444], although one study shows an advantage with oxaliplatin [445].

Since 2004, three new biological agents that interrupt cellular pathways have become available for the treatment of metastatic colorectal cancer. Bevacizumab (Avastin) [446] is a humanized monoclonal antibody targeted against vascular endothelial growth factor (VEGF). The interaction of VEGF with its receptors leads to endothelial cell proliferation and new blood vessel formation in in vitro models of angiogenesis.

Bevacizumab binds VEGF and prevents the interaction of VEGF with its receptors on the surface of endothelial cells, with resultant inhibition of tumor angiogenesis. Cetuximab (Erbitux) [447] is a chimeric monoclonal antibody that binds to epithelial growth factor receptors preventing the activation of tyrosine kinase and affecting pathways regulating cell proliferation and apoptosis. In clinical studies bevacizumab

IFL	[448]	35	6.2	15.6
IFL plus Bev	[448]	45	10.6	20.3

FOLFIRI = 5-fluorouracil + leucovorin + irinotecan (every 2 weeks).
FOLFOX6 = 5-fluorouracil + leucovorin + oxaliplatin.
IFL = 5-fluorouracil + leucovorin + irinotecan (every 6 weeks).
Bev = bevacizumab.
From ref. [452].

leads to a prolongation of overall survival when added to irinotecan, 5-FU, and leucovorin (IFL) [448] or when added to FOLFOX [449] in patients intolerant to irinotecan. Consequently, bevacizumab has been FDA approved in combination with any intravenous fluorouracil-containing regimen as initial therapy for patients with advanced colorectal cancer. The application and benefit of cetuximab is less clear. Cetuximab used in combination with irinotecan in patients with metastatic colorectal cancer previously refractory to irinotecan showed an improved tumor response rate and median time to tumor progression compared with patients treated with cetuximab alone [450]. Trials of this drug in 5-FU-based regimens are under way. In 2006, panitumumab (Vertibix) was approved by the FDA for treatment of patients with metastatic colorectal cancer refractory to standard chemotherapy. Panitumumab as a monotherapy significantly improved progression-free survival in these patients compared with supportive care [451]. Panitumumab, a fully human monoclonal antibody, targets epidermal growth factor receptors, similarly to cetuximab.

Three combinations of chemotherapy have shown efficacy as first-line treatment for patients with stage IV colorectal cancer: FOLFOX, FOLFIRI, and IFL with bevacizumab. Clinical superiority has not been established among these regimens and the treatment choice is left to the physician and his or her assessment of the patient's comorbidites [452]. However, IFL with bevacizumab is a less favored option because of greater toxicity than the other two chemotherapeutic regimens. Although patients with metastatic disease have been treated with continuous chemotherapy there appears no benefit to this strategy versus a planned duration and restarting with recurrent disease. Other agents under study include cyclooxygenase inhibitors in combination with conventional chemotherapy, inhibitors of VEGF receptors, tubulin binders, and topoisomerase inhibitors, to name a few.

Prognostic factors

Introduction

A variety of clinical, pathological, serological, and molecular variables have been evaluated as prognostic (linked to outcome) and predictive (predicting response to therapy) factors in patients with colorectal cancer (Table 65.14). A consensus

Table 65.14 Prognostic factors in colorectal cancer

Worsens prognosis	Improves prognosis	No proven association
Clinical factors		
Bowel perforation at diagnosis	Asymptomatic at diagnosis	Nausea, vomiting at diagnosis
Bowel obstruction at diagnosis		Abdominal pain at diagnosis
Diabetes mellitus		Bowel habits change at diagnosis
		Red cell transfusions
Pathological factors		
Increasing extent of local invasion (T stage) (I)[a]	MSI histology (intratumoral and peritumoral lymphocytes) (IIB)	Tumor size (IV)
Lymph node metastasis (N stage) (I)	Tumor grade, well-differentiated (IIA)	Tumor gross configuration (IV)
Blood or lymphatic invasion (I)		
Residual tumor following surgery with curative intent (R stage) (I)		
Residual tumor in margin after neoadjuvant chemotherapy (IIA)		
Signet-cell histology (IIB)		
Small-cell histology (IIB)		
Serological factors		
Elevated carcinoembryonic antigen levels preoperatively (I)		Tumor-associated proteins or carbohydrates (III)
Elevated postoperative carcinoembryonic antigen levels (I)		
Molecular factors		
18q loss (IIB)	MSI (IIB)	
p53 gene mutation (III)		
Thymidylate synthase overexpression (III)		
KRAS mutation (III)		

a Parentheses are American College of Pathology categories.
MSI, microsatellite instability.

statement of the College of American Pathologists [453] rates many of these as:

- Category I – definitely proven and generally used in patient management
- Category IIA – repeatedly shown to have value and should be noted in the patient report but need validation in statistically robust studies
- Category IIB – promising but present investigation lacks sufficient data for clinical use
- Category III – indeterminate value
- Category IV – well studied with no value.

Clinical factors

At diagnosis of colorectal cancer, asymptomatic patients have a better 5-year survival rate than symptomatic patients, 71% vs 49%, respectively [323,324]. Also, patients presenting with bowel obstruction or bowel perforation have a statistically significantly poorer prognosis than those patients without these symptoms as adjusted for Dukes stage. Other presenting complaints, including nausea and vomiting, change in bowel habits, or abdominal pain, are not independent prognostic factors [317]. Patients with stage II or stage III colorectal cancer and diabetes mellitus have a 42% increased risk of death from any cause, and a 21% increased risk for cancer recurrence compared with those without diabetes [454]. Long debated has been the influence of blood transfusion on colorectal cancer, thought to cause increased tumor recurrence as a consequence of immunosuppression of the patient. However, data reveal no impact on disease recurrence with blood components/red blood cell transfusions [455].

Pathological factors

Among all prognostic factors, the pathological TNM stage of colorectal cancer at diagnosis is the most important [456]. The local extent of the tumor (T), regional lymph node metastasis (N), blood or lymphatic vessel invasion, and residual tumor following surgery with curative intent are category I factors. With increasing pathological stage comes decreasing 5-year survival rate (Table 65.14). Also, interaction between tumor invasion and lymph node positivity with regard to prognosis occurs. In patients with one to three lymph nodes positive on pathological review (N1), the depth of invasion influences prognosis. Stage IIIA (T1/T2, N1) patients have a better 5-year survival (59.8%) than stage IIIB (T3/T4, N1) patients (42.0%). Moreover, those with stage IIIC (any T, N2) with 4–12 lymph nodes positive have a poorer 5-year survival (27.3%) regardless of tumor invasion compared with those with less lymph node involvement [456]. The accuracy of staging is related to the number of lymph nodes reviewed; high miss rates of lymph node metastasis occur if fewer than 15 nodes are examined. Consequently, pathology societies recommend that at least 12 lymph nodes be examined to provide accurate staging [457]. Lymph nodes are examined by microscopic review after traditional hematoxylin–eosin staining. More sophisticated evaluation for micrometastases by immunohistochemistry or molecular techniques is not recommended [456]. The prognostic importance of tumor involvement with blood or lymphatic vessel invasion is well documented with respect to malignant polyps, and found to be associated with regional lymph node involvement. Also, microscopic residual tumor left after attempted curative surgery is highly predictive of recurrence.

Histological features found to have value but needing validation are histological grade and type. The assessment of histological grade (well differentiated, moderately differentiated, poorly differentiated, and undifferentiated) is hampered by lack of a uniform grading system. Certain histological types of tumors, including signet ring [458] and small cell tumors [459], carry an adverse prognosis. In a review of 2995 serial colorectal cancers, signet cell pathology was found in 1.1% of cancers, and the 5-year survival of these patients was only 9.1% [458]. By contrast, the histology noted with MSI-H tumors with intratumoral lymphocytes, peritumoral lymphoid reaction, and transmural Crohn's-like lymphoid reaction is associated with a more favorable prognosis [460]. Interestingly, the tumor size and location are not of prognostic significance.

Serological factors

Carcinoembryonic antigen (CEA)

Carcinoembryonic antigen is a high molecular weight glycoprotein with multiple subtypes consisting of a series of immunoglobulin-like domains [461,462]. It has many putative functions including cell adhesion, immunity, and apoptosis, and is thought to enhance metastatic potential [462,463]. The initial study of CEA touted this compound as a serum marker with high sensitivity and specificity for colorectal cancer [463]. Subsequent reports noted a sensitivity for Dukes A and B colorectal cancer of 30%–40%, and estimated that for every valid colorectal cancer detected by CEA analysis there would be 250 false-positive tests [464]. Consequently, multiple consensus committees have recommended against using CEA as a screening test for colorectal cancer [465,466]. Likewise, CEA is not a diagnostic test for colorectal cancer, again because of low sensitivity and elevation of this marker in patients with liver disease and normal cigarette smokers.

Although not beneficial as a screening or diagnostic test, CEA levels are useful for assessing prognosis and postoperative surveillance. Colorectal cancer patients with high preoperative levels of CEA have a worse prognosis than those with low levels independent of tumor staging [467,468]. The recurrence rate of colorectal cancer was higher in those with CEA levels greater then 5 ng/mL, with a linear inverse correlation between preoperative levels (2–70 ng/mL) and time to recurrence (30–9.8 months) with Dukes B and C lesions. Also, two prospective studies confirmed the prognostic value

of CEA in Dukes B (stage II) colorectal cancer patients [461,469]. In one large investigation of 572 node-negative patients (T1,2,3, or 4, N0, M0) multivariate analysis concluded that the preoperative CEA level independently predicted survival. Consequently, high CEA preoperative levels may define a subset of stage II patients with poor prognosis that benefit from adjuvant chemotherapy. Also, the failure of an elevated preoperative CEA level to return to normal within 6 weeks after surgery suggests residual or metastatic disease [470]. Finally, postoperative surveillance with serial monitoring of CEA detects recurrent or metastatic disease with a sensitivity of about 80% and provides an average lead time of 5 months. Metaanalysis of intensive versus nonintensive postoperative follow-up in which only CEA and physical examinations were utilized in the intensive arm, revealed significantly better survival in the intensively followed group [471]. Most consensus groups examining this issue recommend CEA testing every 2–3 months for the first 3 years after surgery and then every 6 months for the next 2 years [466,472]. A CEA rise of 30% confirmed with repeat testing in 1 month or rises of 15%–20% persisting over 3 months are considered significant and an indication for prompt work-up for recurrent disease.

In summary, CEA for prognosis of colorectal cancer is rated as a category I factor by the College of American Pathologists [453] and recommended by the American Society of Clinical Oncology [473] and the European Group on Tumour Markers (EGTM) [472]. The latter two groups recommend CEA for postoperative surveillance for recurrent cancer. No consensus group recommends CEA levels for screening or diagnosis of colorectal cancer.

Others

A series of other serum markers have been investigated as prognostic markers in colorectal cancer. These include cancer antigen (CA) 19-9, CA 242, CA 72-4, CA 50, TPA (tissue polypeptide antigen), TPS (tissue polypeptide-specific antigen), and tissue inhibitor of metalloproteinase 1 (TIMP-1). Insufficient data exist to recommend the clinical use of these for the detection of early colorectal cancer or for prognosis or surveillance of recurrent tumor.

Molecular factors

Microsatellite instability (MSI)

Microsatellites are regions of DNA in which short sequences of nucleotides, most often dinucleotides, are commonly repeated. Microsatellite instability is the phenomenon of gain or loss of repeated nucleotides in these microsatellite regions. The presence of high-frequency microsatellite instability (MSI-H) (instability at 40% or greater of microsatellite loci tested) in the DNA of a colorectal cancer but not seen in the adjoining normal colonic mucosa can suggest functional loss in one of the MMR genes. This can result from inactivation of both alleles of the gene by a combination of coding region mutations, LOH, or promoter methylation. Microsatellite instability is noted in about 20% of patients with sporadic colorectal cancer [474], and in 90% of those with HNPCC. In the former, MSI is usually caused by somatic methylation of the promoter region of the *MLH1* gene, and in the latter by germ-line mutation of one of the MMR genes.

Patients with MSI-H colorectal cancers have better survival adjusted for stage than those with microsatellite-stable tumors [460,475,476]. In a study of 607 patients with colorectal cancer (17% with MSI-H tumors), MSI was an independent prognostic factor of survival; overall 5-year survival was 22% greater for those with MSI-H compared with those with microsatellite-stable (MSS) tumors; moreover, this improved outlook applied to patients at any stage of disease [460]. The association between tumor MSI status and response to chemotherapy is unclear. Four of six published studies correlating microsatellite status and adjuvant chemotherapy report improvement in overall survival in MSI-H patients with 5-FU-based therapy, but questions have been raised concerning the methodology in some of these reports [477–480]. By contrast, one trial analyzing 570 tissue blocks from patients with stage II and stage III colorectal cancer found that 5-FU-based adjuvant chemotherapy benefited patients with MSS or MSI-low tumors but not MSI-H malignancies [481] (17% lower 5-year survival in patients with MSI-H tumors taking adjuvant chemotherapy compared with patients not receiving chemotherapy). With respect to patients with stage IV disease, two retrospective studies report higher response rates in patients with MSI-positive tumors [482,483]. In summary, MSI is considered a prognostic factor with promise but there are insufficient data for it to be used in patient management (category IIB).

Chromosome 18q

Alterations of chromosome 18q (location of the *DCC*, *SMAD2*, and *SMAD4* genes) by allelic loss or LOH appear important in the clinical outcome of colorectal cancer patients. In stage II colorectal cancer the status of 18q appears to have strong prognostic value. The prognosis in those with chromosome 18q allelic loss is similar to stage III cancer, and therefore these patients may benefit from adjuvant chemotherapy. By contrast, those without loss at 18q have a survival rate similar to stage I disease and may not benefit from treatment [484]. In stage III patients with MSS tumors the 5-year overall survival rate after 5-FU-based chemotherapy was almost three-fold higher in patients with tumors with LOH of 18q compared with those with retained 18q alleles [485]. The College of American Pathologists considers LOH of 18q a category IIB prognostic factor.

p53 gene

The *p53* tumor suppressor gene located on chromosome 17p is frequently somatically mutated (40%–60%) in sporadic colorectal cancers. In the presence of cell damage, the p53

protein functions to activate DNA repair or, if not possible, to eliminate the damaged cell by apoptosis. In the pooled analysis of 28 studies, *p53* overexpression in patients undergoing surgery alone appeared to be a significant factor predicting poorer prognosis compared with those having wild-type *p53* function [486]. Mutation of *p53* has also been associated with a higher risk of cancer-related death in stage III colorectal cancer patients treated with 5-FU-based chemotherapy [487]. Mutation of *p53* is considered a category III prognostic factor.

Thymidylate synthase

Thymidylate synthase (TS) is a target enzyme of 5-fluoropyrimidines. Inhibition of TS leads to interference with DNA synthesis and repair and induction of DNA strand breaks. The promoter region of the TS gene has tandem repeated regulatory sequences that are polymorphic in humans and appear to affect the tissue expression of this enzyme [488]. A number of preclinical studies report that overexpression of TS correlates with insensitivity to 5-FU. However, studies in the clinical setting have been inconsistent regarding the ability of TS expression to predict response of patients to 5-FU-based therapy used in adjuvant or metastatic treatment [489]. Additional study with attention to assay methodology and patient group may further clarify the value of this marker (category III).

Other molecular markers

Because of conflicting evidence, the value of *KRAS* mutations in predicting survival and response to adjuvant treatment is unclear. Other factors such as DNA content, ploidy, or proliferative indices of the tumor are factors not yet sufficiently studied to determine prognostic value (category III).

Other malignant large bowel cancers

Malignancies other than adenocarcinomas rarely arise from the large bowel and account for less than 3% of colorectal tumors. The most common are carcinoid, lymphoma, and Kaposi sarcoma. Others include leiomyosarcoma, melanoma, squamous cell cancer at the anorectal junction, and cloacogenic cancers. Carcinoid tumors most commonly occur in the appendix, rectum, and cecum as mucosal or submucosal nodules, several millimeters in size, and pursue an indolent course (see Chapter 54). Kaposi sarcoma in those with human immunodeficiency virus (HIV) disease manifests as red- or violet-colored mucosal lesions (see Chapter 104).

Colorectal lymphoma is rare, representing only 0.9%–1.2% of all colon cancers and occurring in about 14% of all cases of gastrointestinal lymphoma [490–492]. Abdominal pain and weight loss are the most common presenting complaints, occurring in 40%–62% of cases; approximately 50% of patients have a palpable mass on abdominal examination [493]. Findings on CT scan can include either discrete bulky masses, focal mural infiltration, or diffuse colonic invasion [494]. The most common site of colorectal lymphoma is the cecum (73%), followed by the rectum. Histological review shows that most patients (40%–60%) have either diffuse large B-cell lymphoma or Burkitt lymphoma. Additional reports note an increase in incidence of other subtypes including peripheral T-cell, indolent (mucosa-associated lymphoid tissue, or MALT), and Hodgkin lymphoma. Of note, the lymphoma subtype called mantel cell lymphoma has been associated with an 88% rate of colonic involvement, prompting the need for colonic evaluation in these patients [495].

An increased risk of gastrointestinal lymphoma is noted in several autoimmune disorders including Sjögren syndrome, rheumatoid arthritis, systemic lupus erythematosus, Wegener granulomatosis, congenital immune deficiency syndromes, and AIDS. Patients with organ transplants and subsequent immunosuppressive therapy have an increased risk of lymphoma, which more often presents as a single discrete lesion than diffuse colonic involvement [496].

Anorectal examination

A careful anorectal examination is an important part of the gastrointestinal evaluation, particularly in patients with constipation or anorectal complaints. Step-by-step explanation, reassurance, and gentle technique help to minimize patient embarrassment and discomfort. The patient should be placed in the left lateral decubitus position with the hips and knees flexed and the buttocks protruding just beyond the edge of the examining table. The prone jackknife position is ideal but requires a specialized examining table and places the patient in a somewhat unfamiliar position. The buttocks, sacral region, and thighs are observed for signs of pilonidal disease, dermatological conditions, and infections. The buttocks are then firmly retracted with both hands to permit inspection of the perianal region. Fistulous openings, fecal or mucus soiling, and excoriations or chronic skin changes give clues to underlying disease processes. Anal pathology such as tumors, skin tags, anal fissures, and prolapsing hemorrhoids should be described with regard to their anatomical location.

Perianal digital palpation may reveal induration, tenderness, or the cord of a fistulous tract. Thereafter, the lubricated index finger is gently inserted into the anus. Anal resting tone can be assessed when the patient relaxes after insertion of a finger into the anal canal. A patulous sphincter raises the possibility of neurogenic injury. Puborectalis function is assessed by palpating the muscle with the ventral aspect of the examining finger; when patients squeeze (or contract) this muscle, the examining finger is lifted upward and anteriorly. Conversely, when subjects are asked to expel the examining finger, the puborectalis should relax and the perineum should descend by approximately 2–3 cm. The digital examination should also evaluate for rectal polyps, tumors, feces, and foreign bodies. The presacral area, the prostate, and even the cul-de-sac region may be palpated. The impression of the cervix or an indwelling tampon on the anterior rectum should not be confused with pathology. The anal "wink" reflex is assessed by observing for sphincter contraction (i.e., a "wink"), in response to gentle stroking of the perianal region or to perianal pinprick.

Findings in fecal incontinence may include reduced anal resting tone, weak squeeze pressures or a reduced puborectalis "lift" when patients squeeze this muscle. Defecatory dysfunction may be suggested by reduced (i.e., < 2 cm) or increased (> 4 cm) perineal descent during simulated defecation. Moreover, the puborectalis or anal sphincter muscle may contract (i.e., dyssynergia) or fail to relax when patients try to expel the examining finger. The anal "wink" reflex may be absent in patients with a large fecal impaction, but persistence of this finding after disimpaction suggests nerve impairment. If the history or examination raise the possibility of a rectal prolapse, pouch of Douglas hernia, or excessive perineal descent that is not apparent in the lateral recumbent position, patients should be examined in the seated position on a commode. Occasionally, adequate examination is impossible except under anesthesia.

Anoscopy is the best means of examining the anal canal. Fistulous openings and anal canal lesions can be identified, and internal hemorrhoids may be visible just above the dentate line, particularly when the patient is asked to bear down. Fissures and perianal lesions may be appreciated as the instrument is withdrawn below the dentate line. Rigid

Textbook of Gastroenterology, Fifth Edition Edited by Tadataka Yamada

proctosigmoidoscopy completely evaluates the distal sigmoid colon and rectum. The rigid instrument is particularly useful for preoperative documentation of rectal cancer, obtaining large-bite rectal biopsy specimens for diagnosis of Hirschsprung disease, removal of foreign bodies, and evaluation of the mucosa if fiberoptic or video endoscopic equipment is unavailable. For most other indications, the flexible instrument is preferred.

Hemorrhoids

Anatomy and epidemiology

Hemorrhoids result from dilation of the superior and inferior hemorrhoidal veins. These veins form hemorrhoidal plexuses, or cushions, in the submucosal layer of the lower rectum and are essential to the normal function of the anal canal. In the United States, estimates of symptomatic hemorrhoids range from 4.4% of the general population to as high as 50% of adults over the age of 50 years [1]. Symptoms of constipation (i.e., excessive straining at defecation, sense of incomplete evacuation, and repeated toilet visits), but not self-defined constipation, are associated with hemorrhoidal disease [2,3].

Hemorrhoids are either internal or external. Internal hemorrhoids arise from the superior hemorrhoidal venous plexus above the mucocutaneous junction, or dentate line, of the anorectum. They are covered with rectal mucosa and occur in three primary locations: right anterior, right posterior, and left lateral, although anatomical variability is common. The end branches of the superior and middle hemorrhoidal arteries terminate in the submucosa above the dentate line, with an anterior and posterior branch on the right and a single lateral branch on the left. The right posterior and left branches give off two end branches to form potentially secondary hemorrhoids. External hemorrhoids arise from the inferior hemorrhoidal venous plexus below the mucocutaneous junction and are covered by squamous epithelium. The perianal squamous epithelium contains numerous pain receptors, so that thrombosis of external hemorrhoids causes significant pain. Internal and external hemorrhoidal plexuses freely communicate to drain into the inferior vena cava through the internal pudendal veins.

Pathogenesis

Histologically, hemorrhoids consist of three important parts: the lining (rectal mucosa or squamous epithelium), stroma (blood vessels, smooth muscle, supporting connecting tissue), and anchoring connective tissue, which secures hemorrhoids to the sphincter apparatus. With age or other aggravating factors, the anchoring and supporting connective tissue deteriorates, causing hemorrhoids to bulge and descend, leading eventually to symptoms [4]. This sequence of events is supported by the increased incidence of hemorrhoids in patients with chronic constipation, diarrhea, pregnancy, or pelvic tumors – conditions that chronically or recurrently increase pelvic venous pressure. In some individuals, the internal anal sphincter becomes hypertrophic and the anal outlet becomes functionally narrowed. During straining, the fecal bolus acts as an obturator in forcing the hemorrhoidal cushions to descend through the hypertrophic sphincter, enlarge, and become symptomatic.

Definitions

External skin tags are redundant folds of skin that arise from the anal verge when thrombosed external hemorrhoids resolve spontaneously. Internal hemorrhoids may be classified as follows:

- Grade I hemorrhoids bulge into the lumen of the anorectal canal on anoscopy but do not prolapse.
- Grade II hemorrhoids prolapse out of the anus with defecation or straining but reduce spontaneously.
- Grade III hemorrhoids prolapse with defecation or straining and require manual reduction.
- Grade IV hemorrhoids are irreducibly prolapsed and are at risk for strangulation [5].

The clinical presentations and recommended therapies for these groups of hemorrhoids are discussed later.

Diagnosis and treatment

External skin tags

Following thrombosis of an external hemorrhoid, the overlying skin becomes redundant and this excess skin remains after the underlying clot resolves. Skin tags may also arise de novo in cases of inflammatory bowel disease. Symptoms include a palpable growth near the anus and difficulty with anal hygiene, which may be associated with pruritus ani. Skin tags are relatively easy to distinguish from anal cancer or condylomata acuminata by their gross appearance as normal skin and their soft, fleshy texture on palpation. Treatment is conservative and surgical excision is considered only in cases of poor hygiene or because of patient anxiety.

External hemorrhoids

Thrombosis of an external hemorrhoid can cause extreme pain due to distention of overlying perianal skin and inflammation associated with the process of thrombosis. Bleeding may occur after the overlying perianal skin ulcerates and the resolving liquefied hematoma extravasates. External hemorrhoids should be distinguished from strangulated internal hemorrhoids, which tend to be larger and more circumferential, encompassing the entire anus.

Many thrombosed external hemorrhoids can be treated with warm sitz baths two to three times per day. Stool-softening agents, such as psyllium, synthetic mucilloides, and the sodium or calcium salts of dioctyl sulfosuccinate, can minimize straining at stool and prevent aggravation of the pain and thrombosis [5]. Topical anesthetic ointments and witch hazel-impregnated pads may provide additional relief.

Attribution of clinical improvements to medical therapy must be tempered by the knowledge that most thrombosed external hemorrhoids resolve within 48–72 h.

If pain is severe and the patient is seen within 72 h of symptom onset, surgical evacuation or excision of the thrombosed external hemorrhoid can be performed under local anesthesia or occasionally in the operating room; it offers the most rapid relief from symptoms, a lower incidence of recurrence, and longer remission intervals than conservative therapies [6]. After the thrombus has organized or if more than 72 h have elapsed, it cannot be evacuated and conservative therapy is required.

Internal hemorrhoids

Internal hemorrhoids may be associated with discomfort, pruritus ani, fecal soiling, or varying degrees of prolapse. Bleeding, however, is the typical complaint that brings patients to the physician. Hemorrhoidal bleeding is described as bright-red spotting on the toilet tissue or dripping into the toilet bowl. It most often occurs at the end of defecation and is separate from the stool. Rarely, acute severe bleeding requires transfusion and, occasionally, ongoing chronic losses cause iron deficiency anemia [7]. Importantly, hemorrhoids should not be considered the source of hematochezia until other potential bleeding sources in the colon and rectum have been investigated. With the possible exception of a young patient with a bleeding pattern typical of hemorrhoids, a flexible sigmoidoscopy or, if clinically appropriate, a full colonoscopy should be performed. Occult bleeding should never be attributed to hemorrhoids.

Prolapse of hemorrhoids manifests along a continuum of symptoms ranging from difficulty with anal hygiene to painful strangulation. Prolapsed hemorrhoids should be distinguished from rectal mucosal prolapse and from prolapse of rectal polyps or cancer. Sigmoidoscopy with biopsy of suspicious lesions should be carried out if appropriate. Anal condylomas and anal cancer are easily differentiated from prolapsing internal hemorrhoids, and thrombosed external hemorrhoids cause pain as a presenting symptom.

All degrees of internal hemorrhoids may be associated with mild discomfort, but only strangulated hemorrhoids cause significant pain. Strangulation occurs secondary to prolapse with subsequent lack of blood supply. Progression to gangrene with resultant infection is life threatening and will occur if immediate surgical therapy is not instituted. In contrast to complete rectal prolapse, strangulated hemorrhoids lack concentric mucosal folds and cannot be reduced.

Topical agents are effective for most first- and second-degree hemorrhoids, including those that bleed intermittently. A high-fiber diet and adequate fluid intake helps to promote passage of soft bulky stools to minimize straining [5]. Some patients benefit from the addition of hydrophilic bulk-forming agents such as psyllium extracts or mucilloids. Excessive and prolonged defecatory straining should be discouraged. Many patients also benefit from warm sitz baths twice daily and attention to proper anal hygiene. A number of proprietary agents, such as suppositories, ointments, and hydrocortisone or anesthetic-containing preparations (benzocaine, lidocaine, pramoxine [pramocaine], dibucaine) offer short-term relief from pruritus, burning, and soreness, although firm efficacy data are lacking. Purified flavonoids derived from citrus fruits or as a traditional medicine derived from the ginkgo tree have been reported to be effective for the short-term relief of acute bleeding [8]; they are advocated as a short-term bridge to more definitive therapies.

If conservative therapy does not suffice, a definitive procedure is necessary (Table 66.1). These are classified into office-based treatments and surgical hemorrhoidectomy. In general, grade I and II hemorrhoids can be treated without removal of redundant hemorrhoidal tissue, whereas grade III and IV hemorrhoids usually require a form of therapy that results in both thrombosis of the hemorrhoid and removal of redundant tissue.

Rubber-band ligation

First described as a rapid, simple, effective device for the treatment of internal hemorrhoids in the outpatient setting [9], rubber-band ligation (RBL) is associated with both

Table 66.1 Nonoperative procedures for internal hemorrhoids

Modality	Grade	Advantages	Disadvantages
Rubber band ligation (RBL)	I, II, some III	Lowest recurrence rate Removes redundant tissue	Discomfort. Rare local complications especially if immunocompromised
Injection sclerotherapy	I, II, some III	Minimal discomfort Technically easy	Rare local complications. Poor long-term benefits
Infrared coagulation	I, II, III	Minimal discomfort	Several applications required. More expensive than RBL
Laser photocoagulation	I, II, III	Minimal discomfort	Expensive
Electrocoagulation	I, II, III		Long application time. Recurrence rates: 25%–35%
Cryosurgery	I, II, III	None	Pain and complications common. Less patient satisfaction

thrombosis of the hemorrhoid and removal of redundant mucosal tissue. By inducing submucosal scarring, development of new hemorrhoidal tissue is prevented. This procedure is effective for refractory grade I hemorrhoids, all grade II, and selected grade III hemorrhoids. Grade IV hemorrhoids are not well treated by this method.

After an anorectal evaluation, the anoscope is inserted and a hemorrhoidal cushion is selected for band application. No anesthetic is required if care is taken to place the band at least 0.5 cm above the dentate line. Some authors recommend banding of only one column per session to minimize tissue necrosis, but up to four ligations may be performed with acceptable morbidity.

In a metaanalysis of 18 prospective randomized trials, RBL was the most effective of the office-based procedures, with a lower recurrence rate than other procedures without anesthesia [10]. The ability to perform RBL in the clinic setting makes this a popular treatment option for patients with hemorrhoids. Inexpensive, plastic, single-handed ligators have been developed to capture the hemorrhoidal tissue for band placement [11,12]. A Cochrane review concluded that RBL is the treatment of choice for grade II hemorrhoids, while reserving hemorrhoidectomy for grade III hemorrhoids or for recurrences after RBL [13].

Injection sclerotherapy

The use of sclerosants, such as sodium morrhuate or sodium tetradecyl sulfate, is an accepted treatment for grade I and II bleeding hemorrhoids. The sclerosant is injected into the submucosal space but not into symptomatic hemorrhoids. An intense inflammatory reaction results in fixation of the mucosa to the underlying muscle, thus obliterating the submucosal layer where hemorrhoids form. Complications are mucosal slough, prostatic infection, contact hypersensitivity, and rectal infection. A refinement of sclerotherapy uses a flexible endoscope to inject saline through a sclerotherapy needle into the hemorrhoidal cushion. Sclerotherapy provides good short-term benefits but with long-term benefits in only 28% of patients [14]. Thus, RBL appears to be a superior choice for grade II hemorrhoids.

Cryosurgery

Special cryoprobes activated by liquid nitrogen, carbon dioxide, or nitrous oxide have been used to destroy local tissue by freezing and subsequent necrosis. If deep freezing of the submucosal hemorrhoidal cushions does not occur, symptoms persist. Tissue damage is uncontrolled and wound healing is accompanied by prolonged anal drainage, late bleeding, and pain. Compared with RBL, patient satisfaction is less and local complications more frequent [5].

Electrocoagulation

Both direct and bipolar current are particularly useful in grade I, II, and III hemorrhoids. The advantage of bipolar current (Bicap) is that applications last only several seconds (vs 8–10 min with direct current) and thermal injury to remote sites is avoided. Both techniques are associated with minor complication rates of 10% and recurrence rates of 25%–35% [15].

Photocoagulation

Infrared light and lasers have been used to treat symptomatic hemorrhoids by stimulating fibrosis of the submucosal layer to cause tissue coagulation and necrosis. Advocates of photocoagulation cite the lack of electrical contact with the patient's body and a more controlled application of destructive force compared with electrocoagulation. Infrared devices are much less expensive than laser devices but both are more expensive than equipment for RBL or injection sclerotherapy. The incidence of discomfort and complications compares favorably with those of RBL and injection sclerotherapy. Rubber-band ligation produces more posttreatment pain than infrared photocoagulation, but fewer patients are likely to need retreatment for symptomatic recurrences, especially in the presence of substantial prolapse.

Hemorrhoidectomy and hemorrhoidopexy

Fewer than 10% of patients with symptomatic hemorrhoids require surgical intervention. Hemorrhoidectomy is reserved for patients who relapse or fail office procedures, as well as most grade III and all grade IV and strangulated hemorrhoids. Hemorrhoidectomy is the most effective of available treatments but has the highest complication rate and the most postoperative disability [5].

The development of stapled hemorrhoidopexy [16] has been a major advance in the treatment of symptomatic internal hemorrhoids. Its advantages include less postoperative pain, shorter recovery times, and long-term outcomes similar to those of surgical hemorrhoidectomy [17,18]. It is therefore considered by some to be the procedure of choice for symptomatic internal hemorrhoids and prolapse [5]. It is not effective for large external hemorrhoids and should be avoided in patients who engage in anoreceptive intercourse, because staples occasionally remain in the area and may cause discomfort [19].

Ablation of the internal anal sphincter

Two strategies have been employed to decrease the abnormally high resting anal pressure found in some patients with hemorrhoids. Forceful anal dilation under general anesthesia (Lord procedure) causes variable and uncontrolled damage to the anal sphincters with resulting fecal incontinence. It is less optimal than the more controlled disruption achieved with lateral internal sphincterotomy (see "Anal fissure" below.)

Anorectal varices

Histological studies have shown that anorectal varices and hemorrhoids are unrelated [20]. Rectal varices represent

enlarged portosystemic collaterals that correlate with portal hypertension and develop from hepatofugal portal venous flow through the inferior mesenteric vein to the superior hemorrhoidal veins [21]. Rectal varices represent the communication between the superior hemorrhoidal veins (portal circulation) and the middle and inferior hemorrhoidal veins (systemic circulation), which in turn connect by the femoral vein to the inferior vena cava. The distinction of anorectal varices from external hemorrhoids may be difficult. Often, patients with anorectal varices have other manifestations of portal hypertension such as esophageal varices and ascites. Anorectal varices are usually discrete, serpentine, submucosal veins, which, in contrast to external hemorrhoids, are compressible and refill rapidly. They extend from the squamous portion of the anal canal across the dentate line and into the rectum. Nearly 45% of patients with cirrhosis have anorectal varices on endoscopic examination, and the prevalence increases to 75% using rectal endosonography [22]. Bleeding may occur from any portion of the varix and can be massive and life threatening [23].

The optimal management of anorectal varices is unknown. Treatment by underrunning the variceal columns with absorbable suture achieves primary control in most cases and has a low rate of morbidity [23]. Inferior mesenteric vein embolization or ligation has been reported [24]. Ultimately, surgical or transjugular intrahepatic portosystemic shunting may be required [25,26].

Anorectal abscess and fistula

Anorectal abscess and fistula represent the acute and chronic manifestations of suppurative anorectal infection, respectively. An anorectal abscess is an undrained collection of perianal pus, whereas a fistula is an abnormal communication between the anorectal canal and the perianal skin. In most cases, the underlying pathophysiology is thought to be the same and the treatment is essentially surgical.

Etiology and differential diagnosis

The most common cause of anal sepsis is an infection of the anal glands and ducts, perhaps secondary to fecal bacterial plugging of the ducts and obstruction (i.e., the cryptoglandular theory). These glands arise from the anal canal at the level of the crypts of Morgagni, and often penetrate into the intersphincteric space (Fig. 66.1) [27]. Anal trauma, diarrhea, hard stools, or foreign bodies may predispose to glandular obstruction or sepsis. Anal sepsis most frequently affects people in the third and fourth decades [28].

The most common bacterial isolates are *Escherichia coli*, *Enterococcus* species, and *Bacteroides fragilis*. Histological specimens from patients with anorectal fistula revealed infected anal glands 70%–90% of the time. Other conditions associated with anal sepsis include Crohn's disease, malignancy, tuberculosis, actinomycosis, lymphogranuloma venereum, radiation-induced proctitis, leukemia, and lymphoma. Other disease states in the differential diagnosis of suppurative anorectal conditions are infected presacral epidermal inclusion cysts, hidradenitis suppurativa, pilonidal disease, and Bartholin abscesses.

Classification

Anorectal abscesses may be classified according to the site of the suppurative process. Perirectal abscesses inferior to the puborectalis and levator ani are classified as low intermuscular abscesses (i.e., perianal, submucosal, intersphincteric, and ischiorectal abscesses) [29]. Deep postanal and supralevator abscesses are categorized as high intermuscular abscesses. A suppurative process may involve multiple perirectal spaces. For example, the classical "horseshoe" abscess originates in the posterior midline and extends through the intersphincteric and deep postanal spaces to one or both ischiorectal spaces.

The Parks classification system is derived from the cryptoglandular hypothesis and is the system most widely used to classify anorectal fistulae [29] (Fig. 66.1). Based on the course taken by the main tract, fistulae are characterized as inter-, trans-, supra-, or extra-sphincteric. The most common type is intersphincteric, in which the fistula ramifies between the internal and external anal sphincters. Transsphincteric fistulae pass from the intersphincteric plane through the external sphincter and into the ischiorectal fossa. Suprasphincteric fistulae pass upward in the intersphincteric plane, over the puborectalis muscle, and into the ischiorectal fossa. Extrasphincteric fistulae pass from the perianal skin through the ischiorectal fat and levator muscles into the rectum. Division of the entire tract of either suprasphincteric or extrasphincteric fistulae results in total division of the muscles of continence.

Clinical manifestations

Anorectal abscess

Common symptoms include the slow, gradual onset of pain, increasing in intensity to the sensation of pressure and fullness. The pain may be exacerbated by sitting, movement, or defecation. Constitutional symptoms include malaise and fever. Approximately 20%–33% of all patients will have had a previous episode of anorectal sepsis [30].

The physical findings depend on the location of the abscess. An examination under general anesthesia may be necessary to confirm the diagnosis. A perianal abscess generally manifests with localized swelling, hyperemia, induration or fluctuance, and perianal tenderness. Purulent discharge reflects spontaneous drainage. Patients may have fever or malaise, but usually do not have systemic symptoms. Point tenderness and poorly demarcated induration are the most frequent findings. Because of profound granulocytopenia, fluctuant masses are not usually seen in leukemic patients

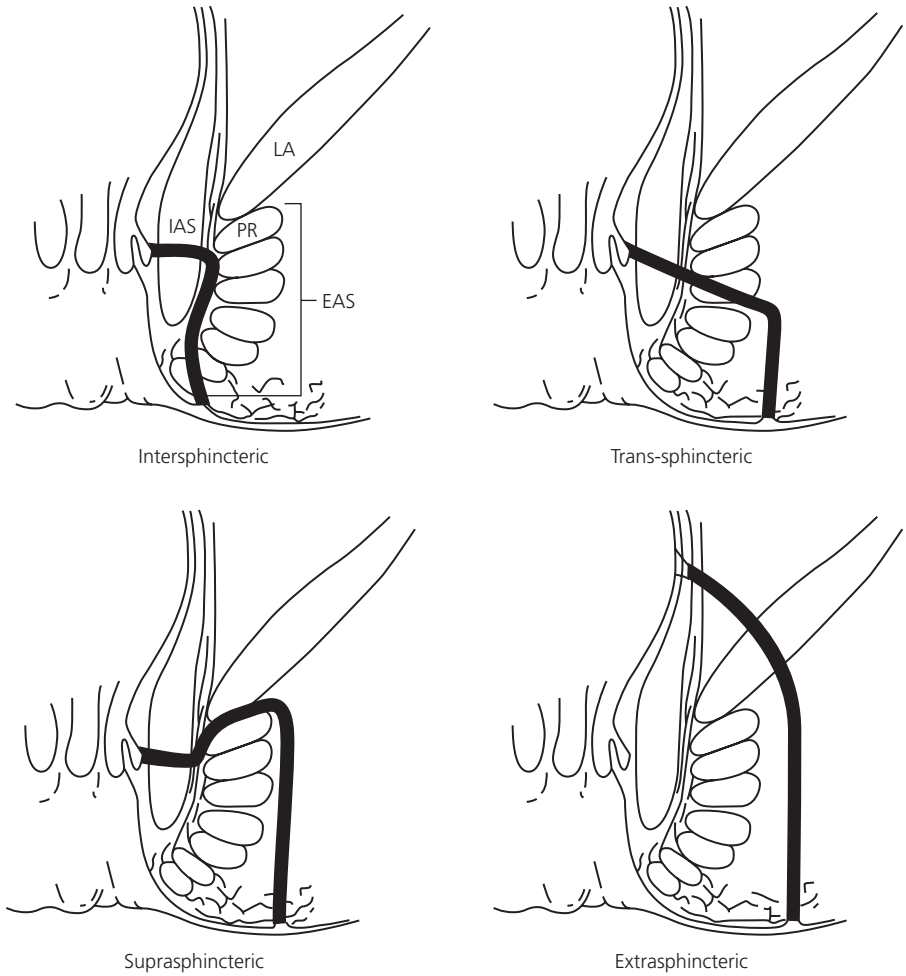

Figure 66.1 Classic location of several fistulas and their relationship to pelvic musculature depicted schematically. Anorectal anatomy: PR, puborectalis; LA, levator ani; IAS, internal anal sphincter; EAS, external anal sphincter.

receiving chemotherapy. Necrosis and tissue breakdown may proceed rapidly with extension into the genitalia and pelvis.

Ischiorectal abscesses may present as small localized swellings. More frequently, the ischiorectal space may accumulate a large volume of purulent material manifest as an erythematous and indurated mass in the buttock. Fever and leukocytosis are common. A large ischiorectal abscess frequently represents a horseshoe extension.

Supralevator abscesses may be caused by an upward extension of a collection in the distal anal canal, or a pelvic abscess secondary to intraabdominal or pelvic pathology (i.e., diverticulitis, appendicitis, or pelvic inflammatory disease). The patient may be systemically ill. A pelvic mass may be identified by rectal or vaginal examination.

Intersphincteric and postanal abscesses may be difficult to diagnose because they are frequently not associated with inflammatory skin changes. An examination under general anesthesia may be required to diagnose these abscesses, particularly because intersphincteric abscesses cause considerable discomfort.

Anorectal fistulae

Patients usually present with intermittent or persistent purulent or serosanguinous discharge from an external opening in the perianal area. The classical symptoms are increasing pain, slight fever, and pain on defecation followed by mucopurulent drainage and a reduction in pain. Chronic discharge may irritate the skin and cause pruritus. Most patients have a previous history of anorectal suppuration.

Fistulous tracts are fibrous inflammatory tubes lined by granulation tissue, with a diameter of 5–7 mm. The assessment should characterize internal and external openings, the course of primary and any secondary tracts, and presence of underlying disease. The external opening is typically a small, perhaps draining pit located close to (i.e., for intersphincteric tracts) or further away from (i.e., for transsphincteric tracts) the anal verge. Multiple external openings suggest multiple complex tracts, often caused by Crohn's disease or hidradenitis suppurativa. The internal opening may be felt as an indurated nodule, most often at the dentate line. Most fistulae can be delineated by gentle probing with anorectal probes

or crypt hooks, preferably in the operating room, and with caution to avoid creation of false tracts, which can complicate evaluation and management.

Diagnostic tests

All patients with anorectal fistulae should undergo sigmoidoscopy to identify the internal opening and associated disease (i.e., inflammatory bowel disease or neoplasms).

Pelvic magnetic resonance imaging (MRI), endoanal ultrasound, and surgical examination under anesthesia were of comparable accuracy (87%–91%) for classifying perianal fistulae in a study of 34 patients with perianal Crohn's disease [31]. When any two modalities were combined, the accuracy increased to 100%. Whereas the 7-MHz linear scanning probe is particularly useful for imaging perianal fistulae, radial scanning provides complementary information and rarely may reveal fistulae not identified by the linear probe. For MRI, the phased-array coil provides better resolution than the body coil. The choice among these modalities is primarily guided by the need for a surgical therapeutic intervention. If, as is often the case, surgical intervention is required, then surgical evaluation combined with ultrasound or MRI is appropriate. The choice between ultrasound and MRI depends on local institutional expertise. When the suspicion of a perianal lesion is low, combining ultrasound and MRI may prevent an invasive exam under anesthesia.

Imaging of perianal fistulae with fistulography in patients with fistula-in-ano, or with pelvic computed tomography (CT) in patients with Crohn's disease, is not sufficiently accurate to be clinically helpful.

Treatment

Anorectal abscesses are surgical emergencies and should be drained expeditiously. Depending on the patient's condition or preferences, this can be done in the office, emergency room, or operating room. The need for drainage is underscored by the observation in one series that the time interval from onset of primary anorectal abscess to necrotizing anorectal infection was up to 5 days, with mortality in excess of 50% [32]. Patients who are neutropenic are particularly susceptible to serious anorectal infection; early diagnosis and aggressive surgical drainage may be life-saving, with improvement in mortality rates to below 10% [33,34]. With the exception of intersphincteric and postanal abscesses with horseshoe extensions, anorectal abscesses may be drained by a simple drainage procedure or by a fistulotomy. Perianal and ischiorectal abscesses are drained externally, whereas submucosal and intersphincteric abscesses are drained internally. For postanal abscesses with horseshoe extensions or intersphincteric abscesses, the drainage technique involves sphincterotomy and fistulotomy in which the infected anal gland is destroyed. Drainage of supralevator abscesses is guided by the track taken by the abscess. Those that result from upward extension of an intersphincteric process should be drained transrectally. By contrast, supralevator collections resulting from cephalad extension of a transsphincteric fistula or an ischiorectal collection should be drained transperineally through the ischioanal fossae.

After a simple drainage procedure, the risk of a recurrent abscess and subsequently an anorectal fistula varies from 11% to 66% [35]. A primary fistulotomy might avoid the need for a second procedure in patients who develop a recurrent abscess or fistula after a simple procedure, with a slightly increased risk for fecal incontinence. Perhaps fistulotomy should be considered in patients who have a history of previous anorectal sepsis or who present with an ischiorectal abscess with an obvious internal opening. If the physician waits for an abscess to point or become ripe, he or she must realize that the risks of necrotizing infection and extension into previously uninfected spaces rise dramatically.

Antibiotics should be used as adjunctive therapy in special circumstances only (i.e., valvular heart disease, immunosuppression, extensive associated cellulitis, and diabetes). Antibiotics that provide gram-negative aerobic and anaerobic coverage (i.e., ticarcillin/clavulanate, piperacillin/tazobactam, or a broad-spectrum cephalosporin) are recommended. Wound isolates are usually polymicrobial with *Escherichia coli, Proteus vulgaris, Bacteroides* species, streptococci, and staphylococci predominating [36]. A high proportion of necrotizing anorectal infections contain *Clostridium* species [32]. Immunosuppressed patients often demonstrate *Pseudomonas aeruginosa* [34].

Anorectal fistulae should be treated surgically because they rarely heal spontaneously. Conservative surgical techniques are usually adequate to drain abscesses, reduce inflammation, and provide relief of symptoms [37]. Surgical diversion of the fecal stream, usually in conjunction with resection of diseased intestine or a local anorectal procedure, is used in selected instances (i.e., in patients with a rectovaginal fistula or complex multiple anal fistulae with considerable inflammation) [38].

For patients with Crohn's disease, medical measures intended to heal perineal fistulae and for more proximal lumenal disease are often used (see Chapter 85). The three essential aspects of surgical management for anorectal fistulae are fistulotomy, use of a seton, and endorectal advancement flaps. Most anorectal fistulae may be adequately treated by a fistulotomy. If the fistulous tract is distal to a majority of the external sphincter, the tract is opened by cautery. However, fistulotomy should be avoided if it is likely to damage a significant portion of the sphincter, and particularly for anterior fistulae. In these circumstances, or when there is an appreciable risk of incontinence or poor healing (i.e., patients with Crohn's disease, chronic diarrhea, incontinence, or compromised immunity), setons are useful. A seton refers to any foreign material (i.e., silk, Penrose drains) that can be inserted into the fistula tract to encircle the sphincter muscles [39]. Setons may be used for marking,

cutting, draining, or staging a fistula. A marking seton allows the surgeon to assess the amount of muscle located above the fistula tract, thereby guiding the decision to proceed with fistulotomy. A draining seton may be used as a bridge to or constitute definite surgical therapy. In the latter circumstance, setons may be left in place for long periods of time permitting epithelialization of tracts. A cutting seton is used gradually to transect the sphincter muscle promoting fibrosis of the tissue surrounding the seton. The muscle is divided by gradually tightening the seton, thereby subjecting the muscle to ischemic necrosis. By dividing the proximal portion of the tract, a "high" fistula may be converted to a "low" fistula leaving the distal tract encircled with a seton for division at a later date.

An advancement flap consists of mucosa, submucosa, and part of the internal sphincter, which after debriding the underlying fistula tract is sutured over the internal defect. Advancement flaps offer a one-stage procedure with quicker healing, limited damage to the sphincter, and minimal risk of anal canal deformity. Fibrin glue has also been used to plug fistula tracts, primarily long fistulous tracts with an external opening amenable to closure, and not caused by Crohn's disease [40].

Postoperative management consists of frequent wound inspection, warm sitz baths, measures to facilitate soft, formed stools – fiber supplementation, osmotic laxatives (e.g., sorbitol) – and judicious analgesia. Wound healing after fistulotomy usually takes 4–8 weeks. The incidence of recurrent fistula is about 3%–7% [28,41], and the incidence of anal incontinence after fistulotomy is 18%–52% [42].

Management of anal fistulae in Crohn's disease requires a judicious blend of surgical and medical therapy (see Chapter 57). Metronidazole (typically 750–1500 mg/day) or ciprofloxacillin (1000 mg/day) for up to 3–4 months are often prescribed for Crohn's disease, based only on uncontrolled case series [43,44]. Uncontrolled data and metaanalysis suggest that azathioprine (2–2.5 mg/kg) and 6-mercaptopurine (1.5 mg/kg) are modestly effective, reasonably safe, and relatively inexpensive [44]. One approach is to treat with antibiotics and azathioprine for 8 weeks in patients who are not toxic or miserable, adding infliximab at 8 weeks if fistulae have not closed completely. For markedly symptomatic patients, infliximab may be started sooner (i.e., at 4 weeks). A controlled trial using infliximab (5 mg/kg) (biweekly [BW]) at 0, 2, and 6 weeks improved 68% and healed 55% of patients compared with those receiving placebo (26% and 13%, respectively) [45]. Thereafter, maintenance infliximab (5 mg/kg every 8 weeks) was more effective for keeping fistulae closed [46]. At 54 weeks, fistulae remained closed in 19% of patients who received placebo and in 36% of patients who received infliximab. The coadministration of azathioprine reduces the incidence of human antichimeric antibodies (HACA) to infliximab. Measures to reduce the incidence of HACA include:

- a three-dose induction regimen followed by systematic maintenance dosing at 8-week intervals
- coadministration of immunosuppressive therapy (azathioprine, 6-mercaptopurine, methotrexate)
- pretreatment with 200 mg of intravenous hydrocortisone [47–50].

Rectal prolapse

Rectal mucosal prolapse refers to abnormal descent of the rectal mucosa (Fig. 66.2). Complete rectal prolapse, or procidentia, indicates intussusception of all layers of the rectal wall through the anus. Occult rectal prolapse refers to internal intussusception without protrusion through the anus. A pouch of Douglas hernia originates in the cul de sac of Douglas and protrudes, via the anterior rectal wall, through the anus.

Mucosal prolapse–hemorrhoids

Symptoms

Initially, the mucosal prolapse is small, occurs only after defecation, and reduces spontaneously. Later, the protrusion becomes larger and may require manual reduction or becomes irreducible, causing seepage of mucus and staining of the underclothes. Erosion and ulceration of the protruding mucosa lead to bleeding. The protruding mass has radiating furrows, which are often associated with internal hemorrhoids. By contrast, a true procidentia has circular furrows. Proctosigmoidoscopic examination is required to exclude tumor, polyps, intussusception, or procidentia.

Treatment

Predisposing or aggravating factors (i.e., constipation, diarrhea, polyps, obstructive uropathy) should be addressed. Rubber-band ligation is effective when prolapsing hemorrhoids are not responsive to medical management (see "Hemorrhoids" above). In the presence of anal incontinence, the results of hemorrhoidectomy are unsatisfactory.

Procidentia

Etiology and pathophysiology

Rectal procidentia begins with circumferential intussusception of the rectum that progressively increases over time. Cinedefecographic observations suggest that the leading edge of the intussusception may be located at 6–8 cm or at 15–18 cm from the anal verge. Factors that may predispose to procidentia include excessive straining during defecation, perhaps due to pelvic floor dysfunction, and anatomical factors (i.e., abnormally low descent of the peritoneum covering the anterior rectal wall, loss of posterior fixation of the rectum to the sacral curve, and lengthening and downward displacement of the sigmoid and rectum) [51]. Other conditions associated with procidentia include pelvic neuropathies. The

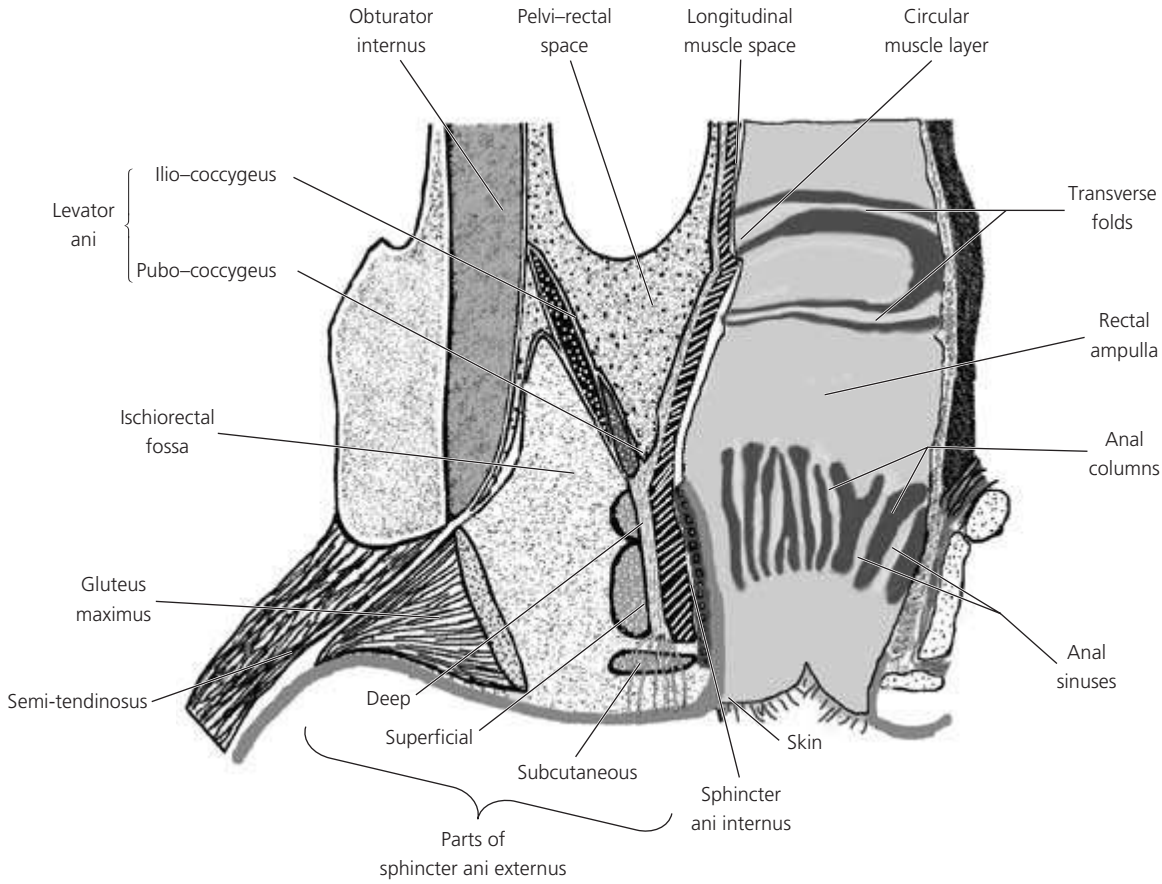

Figure 66.2 Diagram of a coronal section of the rectum, anal canal, and adjacent structures. The pelvic barrier includes the anal sphincters and pelvic floor muscles. From Bharucha [100], with permission from Elsevier.

role of obstetric trauma is uncertain because 40%–50% of women requiring surgery for this condition are nulliparous [52]. Rectal procidentia is rare in men older than 45 years and in women younger than 20 years [53].

Symptoms and diagnosis

The prolapsing mass is initially noticeable with straining only, but over time the prolapse tends to occur with minimal effort. There is usually a feeling of bearing down, or of incomplete evacuation, and often of passage of mucus and bleeding. A majority of patients have constipation, diarrhea, or both. At physical examination, a full-thickness prolapse can be identified by observation and palpation. Although anal resting tone is generally preserved in patients with mucosal prolapse, it is often reduced in patients with procidentia [54]. Denervation of striated musculature on electromyogram, perineal descent, and absence of the anocutaneous reflex are also common findings. If the prolapse is not evident in the left lateral decubitus position, the patient should be examined when straining while seated on the toilet. Proctosigmoidoscopy reveals congestion and edema of the distal rectal mucosa, sometimes associated with a rectal ulcer (see "Solitary rectal ulcer" below).

Attempts should be made manually to reduce a persistently prolapsed rectum to avoid potential complications such as strangulation, ulceration, bleeding, and perforation. Intravenous sedation may facilitate manual reduction. Placing granulated sugar on the prolapsed mucosa often eliminates edema and allows reduction [55]. Gangrene of the anterior rectal wall, a surgical emergency, is occasionally associated with evisceration of small bowel onto the perineum.

Treatment

Because rectal prolapse is generally secondary to excessive straining, and often secondary to defecatory dysfunction, conservative measures (i.e., pelvic floor retraining by biofeedback therapy, a bowel-care regimen) often suffice to ameliorate symptoms of occult rectal prolapse and should be integrated with surgical management. Surgical treatment of rectal prolapse is necessary to avoid complications and ongoing

damage to the pelvic floor and sphincter muscles. The surgical approach is guided by the severity of prolapse, surgical risk, and the surgeon's expertise. Combined abdominal proctopexy and sigmoid resection eliminates two of the presumed causes of rectal prolapse by fixing the rectum to the sacral hollow by means of nonabsorbable sutures and removing the redundant sigmoid colon [53]. Although internal anal sphincter pressures and continence may improve after rectopexy [54], about 40% of patients do not regain continence [52]. A systematic review suggested that residual fecal incontinence was less common after abdominal (vs perineal) approaches, and that division (vs preservation) of the lateral ligaments during rectopexy was associated with less recurrent prolapse but at the price of more constipation [56].

Anal fissure

An anal fissure is a tear in the lining of the distal anal canal below the dentate line, occurring most commonly in the posterior midline. It can affect individuals of all ages and both genders. Clinical symptoms include anal pain during and after defecation, often accompanied by bright-red rectal bleeding and pruritus ani. Acute fissures have sharply demarcated, fresh mucosal edges and may have granulation tissue in the base. When fissures fail to heal within 6 weeks, they are generally designated as chronic. Chronic fissures have raised edges, characteristically exposing the horizontal fibers of the internal sphincter muscle at its base. Other findings associated with chronic fissures are external skin tags, hypertrophied anal papillae, and, occasionally, anal stenosis. Fissures may also occur secondary to an underlying disease such as inflammatory bowel disease (especially Crohn's disease), HIV/AIDS, leukemia, anal carcinoma, and, rarely, syphilis or tuberculosis. Secondary fissures are usually found in a more lateral "off the midline" position [57].

Pathophysiology

The elliptical arrangement of the anal sphincter fibers offers less muscular support to the anal canal posteriorly. This predisposes the posterior anal canal to traumatic tears during passage of a large, hard stool. Many fissures heal rapidly but others do not heal and therefore become chronic.

Patients with chronic anal fissure have increased anal resting pressure. Moreover, spontaneous relaxation of the internal anal sphincter occurs less frequently [58]. As the anoderm receives part of its blood supply from arterioles that cross the internal anal sphincter, it was hypothesized that elevated anal resting pressure could reduce perfusion to the anoderm and lead to local ischemia [59,60]. Doppler ultrasound techniques to measure blood flow in the anodermal area demonstrated that the posterior midline of the anal canal had the lowest perfusion of all four quadrants [61]. Subsequently, it was shown that lateral sphincterotomy normalized both elevated sphincter pressures and blood flow to the anodermal area in these patients [62].

Clinical manifestations

Severe pain associated with scant, bright-red rectal bleeding is the hallmark of anal fissure. Pain occurs both during and after defecation ("like passing razor blades or broken glass") and seems disproportionate to the clinical findings. Severe pain may make anoscopy impossible, and even digital examination is difficult without topical anesthesia. The fissure is best identified by simple inspection after spreading the buttocks. Acute fissures are small linear tears oriented perpendicular to the dentate line in the posterior or anterior midline. Off the midline fissures, especially multiple painless fissures, should prompt a search for a secondary etiology including an examination under anesthesia with biopsy and cultures as appropriate [57].

If an acute anal fissure does not heal promptly, certain characteristic secondary features develop, which include a proximal hypertrophic papilla and a sentinel pile or fibrotic nubbin of skin found at the anal verge (i.e., the classic triad of chronic anal fissure).

Treatment

Acute anal fissures

More than 90% of acute anal fissures quickly heal with simple measures. High-fiber diet, stool softeners, and warm sitz baths following bowel movements may provide symptomatic relief [63]. Although topical anesthetic creams have been used to relieve pain, they may delay healing when compared with bran supplements or topical hydrocortisone [64]. In a randomized trial comparing three treatments (sitz baths with bran supplement, 2% hydrocortisone cream only, and 2% lignocaine [lidocaine] ointment only) in patients with acute posterior midline fissures, initial healing rates at 3 weeks were 88% for the sitz bath and bran group, 82% for the hydrocortisone group, and 60% for the lignocaine group [64].

Chronic anal fissures

The development of a chronic anal fissure with its associated anal hypertonicity requires measures designed to reduce the tone of the internal anal sphincter (IAS). This is because less than 10% will heal with conservative measures. Theoretically, reduction of IAS tone permits easier passage of the fecal bolus through the anal canal to decrease repetitive tearing of the fissure, but the primary rationale is to improve vascular perfusion to the anoderm near the fissure. These treatments involve either pharmacological agents or surgical procedures.

Topical nitrates

The use of topical nitrates is predicated on the principle that nitric oxide is a critically important nonadrenergic, noncholinergic neurotransmitter that mediates relaxation of the IAS. Nitrates are donors of nitric oxide, and topically applied

nitrates have been shown to decrease resting anal pressures and increase anodermal blood flow [65].

Although several studies have shown that 0.2% glycerol trinitrate ointment is superior to placebo [66], other studies have been less impressive [67], and several methodological concerns have been raised [57]. Moreover, headaches and light-headedness are common, and some patients cannot tolerate treatment. Overall success rates range from 27% to 85% with follow-ups of 1–29 months [57]. Interestingly, the lowest success rates were reported when topical nitrates were compared with lateral sphincterotomy [68]. Long-term follow-up has been lacking in many studies, and there is no commercially available glyceryl trinitrate product in the United States.

Calcium channel blockers

Calcium channel blockers also reduce IAS tone but have fewer side effects than do topical nitrates. Two randomized (but not placebo-controlled) trials reported healing rates of 95% over 3 weeks for 0.2% nifedipine [69] and 65% after 8 weeks for 2% diltiazem [70]. In another study, the healing rate was higher with nifedipine (89%) compared with glyceryl trinitrate (58%) [71]. Treatment side effects (headache, flushing) were more frequent with glyceryl trinitrate (40%) compared with nifedipine (5%). At 3–4 months, the recurrence rate (approximately 30%–40%) was similar for both agents.

Botulinum toxin

In a randomized placebo-controlled study, 30 patients with chronic anal fissure received two injections of botulinum toxin (20 units into the IAS), which inhibits acetylcholine release from nerve endings, or saline injection [72]. After 2 months, patients who received botulinum toxin showed significantly greater healing rates (73% vs 13%). Four patients in the botulinum toxin arm who did not heal were retreated, and they then healed within 2 months. No recurrences were observed at 16 months of follow-up. Botulinum toxin (20 units injected into the IAS on each side of the anterior midline) was also compared with topical glyceryl trinitrate (0.2% b.d. [twice daily]) in a randomized trial of 50 patients with chronic anal fissure [73]. Healing rates were significantly higher in the botulinum toxin group (96% vs 60%), and resting anal pressures decreased to a greater extent in the botulinum toxin group than in the glyceryl trinitrate group (29% vs 14%) at 2 months. Approximately 20% of patients in the glyceryl trinitrate group reported moderate to severe headaches associated with treatment, but no side effects were noted in the botulinum toxin group. Long-term results suggest that treatment with botulinum toxin is both successful and durable in many patients [74], although in one study the healing rate at 3 years was only 47% [75].

Botulinum toxin injections are generally well tolerated but are contraindicated in pregnancy and during breast-feeding and should be used with caution in patients with neuromuscular disorders [76]. Some believe that botulinum toxin, because it is less expensive and easier to perform than surgical treatment and does not require anesthesia, should be a first-line treatment for chronic anal fissure [76].

Surgery

Surgery is often reserved for patients with persistent symptoms who have failed medical therapy; but in fact it has the highest cure rate of any form of therapy available [77]. The most common procedure is lateral internal anal sphincterotomy (LIS), involving division of the IAS from its most distal end for a distance equal to that of the fissure or to the dentate line. More than 90% of patients heal after LIS, and recurrence rates of anal fissures are between 0% and 25% [57]. The most important determinant of outcome appears to be the extent of sphincterotomy. One study used anal ultrasonography to show a high rate of incomplete sphincterotomy in those patients who developed symptomatic recurrence [78]. Open and closed techniques produce similar reductions of anal pressure and rates of healing [57,79]. The major concern with LIS is the development of fecal incontinence. Approximately 45% of patients experience some degree of incontinence immediately after surgery – flatus (31%), mild fecal soiling (39%), and gross incontinence (23%). However, in a follow-up study, only 6% had minor fecal soiling and 1% experienced loss of solid stool 5 years after surgery [80].

Anal dilation was initially advocated for anal fissures in 1964, and success rates of 87%–100% have been reported [81]. It has been criticized for being poorly controlled and capable of causing significant anal sphincter damage; others report better outcomes using carefully standardized dilation under local sedation [82]. The consensus is that LIS is safer, and at least as effective as dilation.

Anal stenosis

Anal stenosis is defined as narrowing of the anal canal. This narrowing may result from a true anatomical stenosis (stricture) or a functional (i.e., muscular) stenosis. The most common cause for anal stenosis, accounting for 88% of cases in one series, is hemorrhoidectomy [83]. Excessive excision of anoderm and hemorrhoidal rectal mucosa during hemorrhoidectomy leads to scarring and a progressive stricture. When the mucosa is anchored to the anal verge, the stricture is accompanied by a mucosal ectropion, referred to as the "Whitehead deformity." However, the incidence of stenosis with almost all techniques of hemorrhoidectomy is low (i.e., 0% to < 1.5%) [84]. Other causes of benign anal stenosis include recurrent anal fissure, recurrent abscess and fistula requiring surgical treatment, anal Crohn's disease, radiation, excision of perianal skin lesions as in Paget or

Bowen disease, tuberculosis, actinomycosis, lymphogranuloma, and congenital abnormalities [83]. Malignant causes of anal stenosis include anal and rectal cancers, and, less commonly, transmural invasion of the anorectum by a urogenital malignancy.

Difficult evacuation of stool is the most troublesome symptom. Other symptoms include narrow stools, painful defecation, anal digitation during defecation, bleeding from recurrent anal tears, and constipation or obstipation. Digital rectal examination may reveal the stricture, or cause considerable discomfort to the patient. Under the latter circumstance, examination under anesthesia may be necessary. Functional but not structural anal stenosis will open easily under anesthesia alone.

Treatment is based on the severity and location of the anal stenosis. Medical therapy combines bulking of the stool with anal dilation in the office or at home using the finger or calibrated rubber dilators and topical anesthetics. Dilation is an ideal treatment for patients with Crohn's disease or high-risk patients with otherwise weakened external sphincters [84]. Repeated dilation and steroid suppositories may prevent early recurrence, but there are no well-controlled trials addressing this approach. Surgical treatments of anal stenosis include LIS, an advancement flap, or a colostomy [85]. It has been suggested that LIS is used to treat mid and low anal stenosis. However, it does not treat the ectropion, and the procedure may have to be repeated. A variety of flaps, formed with mucosa or skin, are used to manage anal stenosis. Some of these flaps also address the problem of ectropion. Cure rates in excess of 90% are usually seen [83].

Solitary rectal ulcer syndrome

Solitary rectal ulcer syndrome (SRU) is an uncommon and often underdiagnosed chronic benign disorder related to abnormal defecation. The usual presenting symptoms are excessive straining at defecation (often with the passage of mucus and blood) and feelings of incomplete evacuation. The classic description is that of a shallow, discrete ulcer with a hyperemic margin located 7–10 cm from the anal verge on the anterior rectal wall. However, ulcers may be located between a few and 13 cm from the anus, and are occasionally found on the posterior wall. Furthermore, there may be multiple ulcers or only a localized erythematous or nodular area of mucosa rather than a discrete ulcer. Initial misdiagnosis is common as lesions may be mistaken for inflammatory bowel disease or neoplasia [86]. Characteristic histological changes seen on biopsies taken from abnormal mucosa or ulcer margins include fibrous obliteration of the lumina propria, disorientation and thickening of the muscularis mucosae, and regenerative changes in the crypt epithelium [87]. Although most commonly seen in adults, this syndrome also occurs in children [88].

Pathogenesis

Prolonged straining at stool forces the anterior rectal mucosa into the anal canal leading to mucosal congestion, edema, and ulceration. Although patients with SRU infrequently have clinically apparent rectal prolapse, sigmoidoscopy or defecography demonstrates subtle forms of mucosal prolapse and delayed evacuation during defecation in 90% of these patients [89,90]. Patients with SRU have higher sphincter pressures and thicker rectal walls (primarily muscularis propria) than do patients with complete rectal prolapse [91,92]. The anterior wall mucosa (7–10 cm proximal to the anal margin) is often the first and largest part of the intussusceptum as it descends into the anal canal. This corresponds to the usual location of ulceration seen clinically.

Treatment

Complications of massive bleeding, rectal stricture, and even ulcer penetration into the prostate gland have been reported, but are so uncommon that patients should be reassured that the condition is benign [93,94]. Because the prolapsing mucosa is repeatedly traumatized during defecation, it is appropriate to begin treatment by counseling against anal digitation, eliminating straining, and improving bowel habits by increasing dietary fiber intake or administering osmotic laxatives such as polyethylene glycol [95]. Biofeedback therapy to improve pelvic floor coordination during defecation should be considered as first-line therapy for those who fail conservative measures. For patients with associated rectal prolapse, rectopexy or other procedures to eliminate prolapse may be considered [96]. For patients with occult prolapse, surgery is problematic and should be considered only for those with severe complications [97,98].

Fecal incontinence

Introduction

Fecal incontinence (FI) is defined as recurrent uncontrolled passage of fecal material in an individual with a developmental age of at least 4 years. The prevalence of FI in the community ranges from 2% to 15%. Differences among surveys are perhaps explained by differences in the definition of FI, survey techniques, and the age distribution of the population. The prevalence is similar in men and in women [99], but higher in the elderly and in nursing home residents [100]. Fecal incontinence can substantially impair quality of life and contribute to institutionalization [101,102]. Unfortunately, physicians may not always appreciate the devastating consequences of FI because patients are often embarrassed to discuss their symptoms.

Physiology of continence and defecation

Several factors act in concert to maintain continence. Anatomical factors include the anal sphincters and levator

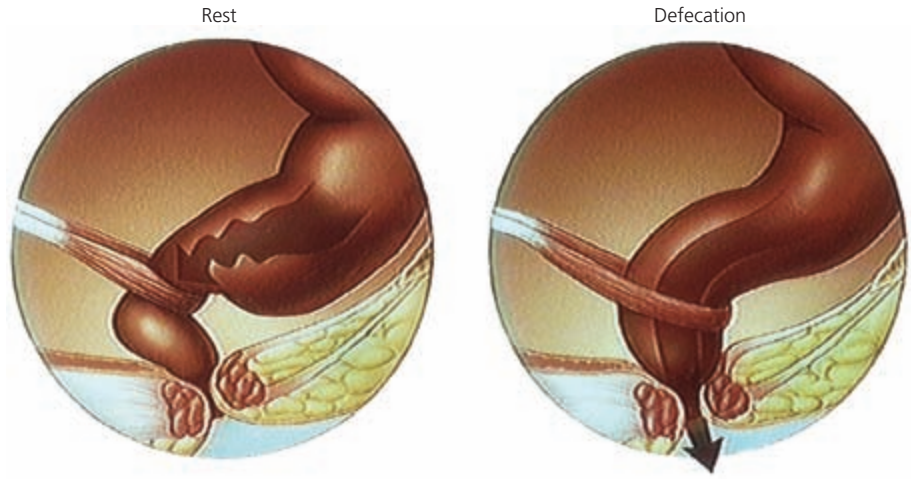

Figure 66.3 Anorectum and puborectalis muscle at rest **(left panel)** and during defecation **(right panel)**. The puborectalis and anal sphincters relax allowing opening of the anal canal and perineal descent during defecation.

ani (i.e., the pelvic floor), rectal curvatures, and transverse rectal folds (Fig. 66.2). The anal canal is 3–4 cm long and normally remains closed as an anteroposterior slit by tonic contractions of the surrounding musculature. Spongy vascular tissues within the canal play a minor, fine-tuning role in fecal continence by assisting with anal closure. The IAS comprises smooth muscle and maintains 70% of the anal resting tone. The external anal sphincter (EAS) comprises striated muscle, which also contributes to resting sphincter tone. The puborectalis maintains the rectoanal angle at rest and contracts further to reduce the angle when subjects squeeze. Stool is often transferred into the rectum by colonic high-amplitude propagated contractions, which tend to occur after awakening or meals [103]. Rectal distention induces reflex relaxation of the IAS. If defecation is convenient, the rectum is evacuated by increased intrarectal pressure coordinated with relaxation of the anal sphincters and pelvic floor muscles (Fig. 66.3). The relative importance of rectal contraction and abdominal wall contraction to increased intrarectal pressure is unclear. Conversely, if defecation is inconvenient, the desire to defecate prompts voluntary contraction of the EAS and pelvic floor, particularly the puborectalis muscle. The desire to defecate dissipates as the rectum accommodates to hold more stool.

Table 66.2 Common causes of fecal incontinence

Anal sphincter weakness
Traumatic: obstetric, surgical (e.g., hemorrhoidectomy, internal sphincterotomy)
Nontraumatic: scleroderma, internal sphincter degeneration of unknown etiology, pudendal neuropathy
Disturbances of pelvic floor
Rectal prolapse, descending perineum syndrome
Inflammatory conditions
Radiation proctitis, Crohn's disease, ulcerative colitis
Central nervous system disorders
Dementia, stroke, brain tumors, multiple sclerosis, spinal cord lesions
Diarrhea
Irritable bowel syndrome, postcholecystectomy diarrhea
Other
Fecal retention with overflow, behavioral disorders

Pathophysiology of fecal incontinence

Fecal incontinence is a heterogeneous disorder, and patients often suffer from more than one deficit of various factors maintaining continence [104,105]. Besides disordered anorectal functions, other factors contributing to FI include disturbed stool consistency, impaired cognition, and decreased mobility.

Impaired pelvic barrier

Anal resting or squeeze pressures may be reduced in FI. Common causes of anal sphincter weakness include sphincter damage, neuropathy, or reduced input from the cerebral cortex or spinal cord (Table 66.2). Although there is a tendency to focus on the anal sphincters, many patients with FI also have generalized pelvic floor weakness, particularly affecting the puborectalis [105–107].

Another manifestation of pelvic floor weakness is the descending perineum syndrome, which results from a combination of obstetric trauma, chronic straining, or neuropathy [106]. The clinical manifestations of the descending perineum syndrome are characterized initially by constipation-predominant symptoms and subsequently by FI. Excessive straining during evacuation may contribute to pelvic floor weakness [108]. Ultimately, excessive descent causes a stretch-induced pudendal neuropathy and widens the anorectal angle, impairing the flap valve that normally maintains continence

when intraabdominal pressure increases. Although sphincter pressures are lower in incontinent compared with continent patients with descending perineum syndrome [109], sphincter pressures do not always distinguish continent from incontinent subjects (see below), underscoring the contributions of disordered rectal compliance, rectal sensation, and stool consistency to FI.

Rectal compliance and sensation

Several studies have demonstrated reduced rectal sensation in some patients with FI. Reduced sensation allows stool to enter the anal canal and perhaps leak before the EAS contracts [104,110]. Conversely, other patients with FI have increased rectal sensation [104,105]. Increased sensation may be attributable to a less compliant or smaller rectum as a consequence of radiation or ulcerative proctitis, but is also found in some women with idiopathic FI. The rectal capacity (i.e., the balloon volume at the maximum imposed pressure), is also reduced in a subset of women with idiopathic FI [105]. Moreover, a smaller rectal reservoir (i.e., reduced capacity or compliance) is associated with the symptom of urgency and with rectal hypersensitivity in FI [111–113]. In irritable bowel syndrome (IBS), increased rectal sensation has been associated with an exaggerated contractile response to rectal distention [114–116]. These observations support in vitro studies indicating that perception of distention is related not to distention but to the contractile response induced by distention [117].

Transient anal sphincter relaxation during or independent of rectal distention enables the anal lining to periodically "sample" and ascertain whether rectal contents are gas, liquid, or stool [118]. There is some evidence to suggest that anal sampling is impaired in FI [118].

Etiology of fecal incontinence

A variety of diseases affect continence mechanisms to cause FI (Table 66.2). In women, FI is often imputed to obstetric anal sphincter injury when endoanal ultrasound reveals IAS or EAS lesions (i.e., scars, thinning, or defects). However, the causal relationship between structural abnormalities and FI is unclear because such abnormalities are often observed in asymptomatic subjects. For example, up to one-third of all women have anal sphincter defects after vaginal delivery [119], but the incidence of postpartum FI is low, ranging from 0% to 10% [100,119]. Clinical observations suggest that many patients with longstanding anal sphincter weakness are asymptomatic until they develop diarrhea. Indeed, among women living in the community, the median age of onset of FI is 55 years [101]. Among community women with FI, 38% had one or more bowel disturbances (i.e., IBS) without rectal urgency, and 14% had rectal urgency with or without bowel symptoms [120]. Disordered bowel habits are more important risk factors for FI than a history of obstetric or surgical anorectal trauma [120]. Although diarrhea is a stronger risk factor for FI, severe constipation with fecal retention may lead to overflow FI. It is conceivable that other factors (i.e., aging, menopause, and chronic straining) may also predispose to FI in this population.

In men, FI is frequently attributable to local causes (i.e., hemorrhoids, fistula, poorly healed surgical scars, sphincterotomy, or proctitis after radiotherapy for prostate cancer). Male FI may also reflect seepage of stool retained in the rectum secondary to a rectal evacuation disorder [121,122] or associated with isolated IAS dysfunction. Several neurological disorders are associated with FI, including diabetic neuropathy, multiple sclerosis, scleroderma, and spinal cord lesions at or below T12. Although anal squeeze pressures are often reduced in multiple sclerosis and diabetic neuropathy, resting pressures are more likely to be reduced in diabetic neuropathy than in multiple sclerosis [123].

Clinical evaluation

A carefully elicited history can help to identify the etiology and pathophysiology of FI, establish rapport with the patient, and guide diagnostic testing and treatment. Bowel habits, stool form, and consistency may be characterized by pictorial stool scales [124]. Semiformed or liquid stools pose a greater threat to continence than do formed stools.

The terms staining, soiling, and seepage may be used to characterize FI [99]. Soiling indicates more leakage than staining of underwear, whereas seepage refers to leakage of small amounts of stool. The circumstances surrounding FI may be characterized as "urge" and "passive" FI. Exaggerated ("urge" FI) or no awareness of the desire to defecate ("passive" FI) before the incontinent episode are associated with more severe weakness of the EAS and IAS, respectively [125]. In addition, rectal urgency may be associated with reduced rectal capacity and increased rectal sensitivity [105,113,126].

The severity of FI can be measured by scales that quantify frequency of stool loss [127]. Because severity may not correlate with quality of life, separate scales have been devised to address these issues. A population-based study demonstrated that the severity of FI can be rated by a simple scale (Table 66.3). Symptom severity rated by this scale strongly correlated with the impact of FI on quality of life [101,102].

The digital rectal examination assesses for anal sphincter defects, anal resting pressure, and voluntary contraction of the EAS and puborectalis when subjects squeeze. Conversely, the puborectalis should relax, and the perineum should descend by 2–4 cm when patients try to expel the examining finger. Examination in the seated position on a commode may reveal rectal prolapse or excessive perineal descent that is not evident when the patient is supine.

Diagnostic testing

Diagnostic testing is tailored to probable etiological factors, response to conservative medical management (i.e.,

Table 66.3 Assessing symptom severity in fecal incontinence

	Symptom severity score			
Symptoms	**1**	**2**	**3**	**4**
Frequency	< 1/month	> 1/month to several times/week	Daily	
Composition	Mucus/liquid stool	Solid stool	Liquid and solid stool	
Amount	Small (i.e., staining only)	Moderate (i.e., requiring change of underwear)	Large (i.e., requiring change of all clothes)	
Urgency or passive incontinence	Neither	Passive incontinence	Urge incontinence	Combined (i.e., passive and urge) incontinence

loperamide or stool softeners), and availability of tests. The strengths and limitations of these tests [100,128] are discussed briefly below.

Endoscopy

Endoscopy to evaluate the rectosigmoid mucosa should be considered in most patients, particularly those with constipation or diarrhea; a colonoscopy may be desirable in certain circumstances and after age 50 for screening purposes.

Anal manometry

Anal pressures at rest and during squeeze are measured with perfused or solid-state transducers using the station pull-through method (Fig. 66.4). Anal pressures should be compared with normal values obtained in age- and gender-matched controls using the same technique [128]. Other factors (i.e., disordered stool consistency, rectoanal sensation, or rectal compliance) should be considered in incontinent patients with normal sphincter pressures.

Endoanal ultrasound

Endoanal ultrasound (US) identifies sphincter thinning and defects that are often clinically unrecognized or amenable to surgical repair (Fig. 66.5, right panel). Interpretation of EAS images is more subjective, operator-dependent, and confounded by normal anatomical variations; and there is substantial interobserver variability. The extent to which clinically occult isolated EAS defects are responsible for fecal incontinence is uncertain.

Evacuation proctography (defecography)

During evacuation proctography, anorectal anatomy and pelvic floor motion are recorded on video with the patient at rest, coughing, squeezing, and straining to expel barium from the rectum. This allows identification of excessive perineal descent, internal rectal intussusception, rectoceles, sigmoidoceles or enteroceles, and puborectalis dysfunction [129]. However, methodology and interpretation are incompletely standardized, and some abnormalities (i.e., a small

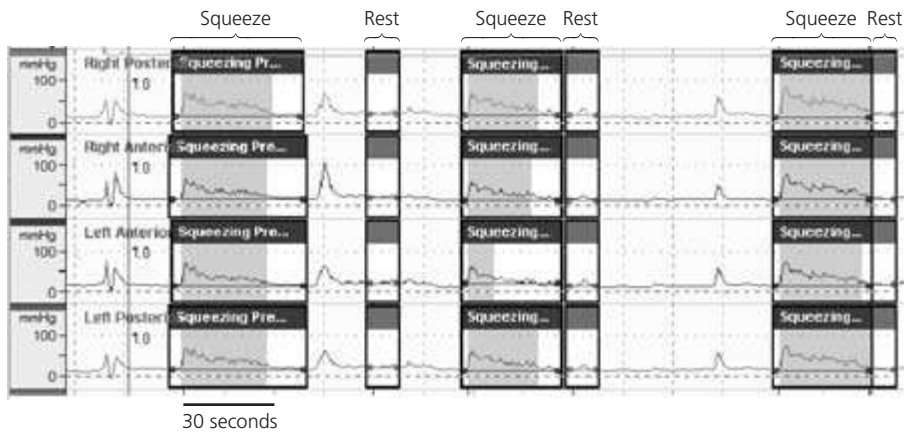

Figure 66.4 Anal sphincter pressures assessed on three separate occasions by four circumferentially oriented transducers stationed 1 cm from the anal verge; transducers were located in separate quadrants. The maximum squeeze pressure is the highest pressure recorded by all four transducers during one of three maneuvers; the average squeeze pressure is calculated by averaging pressures across all four maneuvers. In this example, resting and squeeze pressures were comparable in all four quadrants. From Bharucha AE. Outcome measures for fecal incontinence: Anorectal structure and function. rectocele) are relatively common in asymptomatic older women [128,130]. Despite these limitations, evacuation proctography may be useful in some incontinent patients.

Pelvic magnetic resonance imaging (MRI)

With rapid imaging sequences, MRI can visualize both anal sphincter anatomy and global pelvic floor motion in real time, without radiation exposure [105,131]. Dynamic images are acquired as patients squeeze their sphincters or try to expel ultrasound gel from the rectum, providing a unique assessment of global pelvic floor motion. In contrast to IAS evaluation, MRI performed the same or better than ultrasound for the assessment of the EAS [132]. In one study, 25% of patients, but only 5% of controls, had EAS atrophy [105]. Atrophy of the puborectalis muscle was also more frequent in fecal incontinence (16%) compared with controls (5%). In a small series, patients with EAS atrophy did not fare as well as patients without atrophy after undergoing anal sphincteroplasty for sphincter defects [133].

Pudendal nerve terminal motor latency (PNTML)

Delayed pudendal nerve terminal motor latency (PNTML) is widely used to ascertain if anal sphincter weakness is associated with pudendal nerve injury [128]. However, the validity of measuring PNTML is questionable. There are inadequate normative data, test reproducibility is unknown, and sensitivity and specificity are poor. A consensus committee of the American Gastroenterological Association recommended that PNTML not be used to evaluate for neurogenic injury in FI [128].

Needle electromyography (EMG)

Electromyographic (EMG) mapping of the EAS has been supplanted by endoanal US for identifying sphincter defects. Anal sphincter EMG is useful for identifying neurogenic injury in the EAS, particularly for patients in whom the clinical features suggest a proximal neurogenic process (i.e., in the spinal cord or sacral roots) [105,134].

Rectoanal sensation and compliance

Rectal sensation and compliance can be assessed by progressively distending a rectal balloon. Most laboratories assess sensation by manually distending a latex balloon. Rectal pressure–volume relationships are more accurately assessed by barostat-driven distention of a polyethylene balloon, a technique that is available at selected centers only [135].

In FI, rectal sensation may be normal, reduced, or increased [104,105]. When rectal sensation is reduced, EAS contraction in response to rectal distention may be delayed; these deficits are amenable to biofeedback therapy. Conversely, about 45% of patients with FI have increased rectal sensation [104], which may be partly attributable to reduced rectal capacity and explain the symptom of urgency [105,113,126].

Recommendations

Endoscopy to identify mucosal pathology is probably necessary for incontinent patients with recent-onset diarrhea or constipation; the extent of examination (i.e., sigmoidoscopy or colonoscopy) is also guided by the patient's age and comorbidities. The indications for and extent of diagnostic testing in incontinent patients are evolving. For ambulatory, otherwise healthy patients, anorectal manometry and endoanal ultrasounds can document the severity of weakness and identify abnormal sphincter morphology. Pelvic MRI, combining static and dynamic imaging without radiation exposure, is particularly useful for identifying external sphincter atrophy and pelvic organ prolapse but is relatively expensive and not widely available. Anal sphincter EMG should be considered for incontinent patients with an underlying disease

associated with a neuropathy (i.e., diabetes mellitus, clinical suspicion of a proximal neurogenic process, or sphincter weakness unexplained by morphology as visualized by ultrasound). Pudendal nerve latencies are not useful for investigating FI [128].

As advanced tests (i.e., pelvic MRI, anal sphincter EMG, assessment of rectal compliance and sensation) are not widely available, independently living patients with moderate–severe fecal incontinence should be referred to specialist centers under the following circumstances:

- when symptoms cannot be explained by routine diagnostic tests
- prior to repair of external sphincter defects in older women because surgical repair is not always successful; careful consideration of other factors contributing to incontinence, perhaps supplemented by pelvic MRI to identify external sphincter atrophy may be useful
- for patients who have symptoms of an evacuation disorder and fecal incontinence, biofeedback therapy to improve coordination between abdominal contraction and pelvic floor relaxation is necessary
- for patients who have combined fecal and urge urinary incontinence; sacral nerve stimulation is an FDA (Food and Drug Administration)-approved procedure for urge urinary incontinence, and bowel symptoms may also respond to sacral nerve stimulation [136].

Management

The management of FI must be tailored to clinical manifestations and includes treatment of underlying diseases.

Bowel habit modification

Modifying bowel habits is often central to managing FI effectively. A detailed dietary history may identify excessive ingestion of natural (i.e., prunes) and processed foods (i.e., beverages) that contain fructose and sorbitol and may cause or aggravate diarrhea [137].

Loperamide reduces diarrhea and slightly increases IAS tone, thereby reducing FI [138]. It is important that adequate doses are given (i.e., 2–4 mg, 30 min before meals, up to 16 mg/day). Taking loperamide prior to social occasions is helpful to avoid an accident outside the home. In patients with both constipation and diarrhea, finding the optimal dose to reduce diarrhea but avoid constipation can be challenging. Diphenoxylate is an alternative option for diarrhea [139]. Cholestyramine resin may improve postcholecystectomy diarrhea [140]. A small open-label trial showed that amitriptyline (20 mg p.o. daily) was effective in decreasing FI scores, frequency of bowel movements, and amplitude of rectal motor complexes [141]. The serotonin (5-hydroxytryptamine) 5-HT_3 receptor antagonist alosetron may reduce diarrhea and improve fecal continence in patients refractory to other measures [142]. Patients with constipation, fecal impaction, and overflow incontinence often benefit from a regular evacuation program, using digital stimulation or bisacodyl/glycerol suppositories, fiber supplementation, and selective oral laxatives [143].

Direct pharmacological approaches

Topical application of the α_1-adrenergic agonist phenylephrine to the anal canal increases anal resting pressure. However, in a randomized double-blind placebo-controlled cross-over study of 36 FI patients, phenylephrine did not significantly improve FI or resting anal pressure compared with placebo [66].

Biofeedback therapy

Biofeedback is based on the principle of operant conditioning [144]. Using a rectal balloon–anal manometry device, patients are taught to contract the EAS when they perceive balloon distention; perception may be reinforced by visual tracings of balloon volume and anal pressure, and the procedure is repeated with progressively smaller volumes. A systematic review of 566 patients treated in numerous studies found that 72% of patients resolved or improved symptoms of FI after biofeedback therapy [145]. These studies used heterogeneous methods and outcome measures, and the vast majority were not controlled. A controlled trial randomized 171 patients with FI to four groups: standard medical/nursing care (i.e., advice only); advice plus verbal instruction on sphincter exercises; hospital-based computer-assisted sphincter pressure biofeedback; or hospital biofeedback plus use of a home EMG biofeedback device [146]. Overall, there was no significant difference between the groups, with 54% reporting improved symptoms in the biofeedback groups and 53% in the advice only group. Improvement was sustained at 1 year after therapy; symptoms, resting, and squeeze pressures improved to a similar degree in all four groups. These results emphasize the utility of conservative measures (i.e., patient teaching, emotional support, lifestyle modifications including diet and fluids) and management techniques such as improvement of evacuation, a bowel training program, and antidiarrheal medication for FI. Controlled studies to assess whether biofeedback therapy is efficacious for patients who do not respond to conservative measures alone are in progress.

Surgical approaches

Sphincteroplasty is reserved for a small number of patients with FI, optimally when anal sphincter injury is recognized shortly after an obstetric event. Consensus-based guidelines recommend surgical repair of incidentally recognized anal sphincter defects, often found by imaging years after the presumed obstetric insult. In the short term, overlapping anterior sphincteroplasty improves FI in up to 85% of patients with sphincter defects. However, continence deteriorates thereafter, and far less than 50% of patients remain continent up to 5 years after the operation [147].

Dynamic graciloplasty involves continuous electrical stimulation of the gracilis muscle transposed around the anal canal; electrical stimulation facilitates anal tone by converting type II (fast-twitch, fatigue-prone) to type I (slow-twitch, fatigue-resistant) muscle fibers. Dynamic graciloplasty is approved in Europe but not in the United States. Although FI was significantly improved in roughly 60% of implanted patients, this procedure was associated with significant morbidity, including infections (28%), device problems (15%), and leg pain (13%), which may require reoperation [148,149]. Moreover, up to 50% of patients with functioning graciloplasties may have clinical features of obstructed defecation.

Experience with the artificial anal sphincter is similar; 99 out of 112 implanted patients from a US multicenter report had device-related adverse effects [150,151]. Fifty-one patients required 73 operations to revise the device, and it was explanted in 41 patients (37%). Fecal incontinence scores and quality of life improved; the outcome was successful in 85% patients with a functioning device, and the intention-to-treat success rate was 53%. A systematic review of the artificial sphincter observed that most studies were case series with little or no follow-up of patients in whom the device failed [151]. However, most patients with a functioning device reported clinically significant improvement in continence and quality of life [151]. It is conceivable that the utilization and outcomes with both procedures will increase over time.

A colostomy is the last resort for patients with severe FI; the impact of a colostomy on quality of life in FI has not been formally assessed.

Incontinence products

A Cochrane review concluded that disposable bodyworns with superabsorbent materials (i.e., diaper-type garments or pads) performed better than nondisposable bodyworns in preventing skin condition problems, but these studies focused mainly on urinary incontinence rather than FI [152].

Anal plugs are used for FI in Europe but are not commercially available in North America [153]. In one study, 64% of patients were continent for feces when they used the plug [153]. However, the plug occasionally was displaced in 43%, and 71% experienced discomfort to a varying degree. Plugs need to be removed before bowel movements and are probably not suitable for patients with frequent bowel movements. An inflatable plug with an infrared sensor that detects stool has also been described [154].

New approaches

Predominantly uncontrolled studies suggest that sacral nerve stimulation improves FI, augments anal squeeze pressures more than resting pressure, and may also modulate rectal sensation in incontinent patients [136,155,156]. Sacral stimulation is conducted as a staged procedure; patients whose symptoms respond to temporary stimulation for about 2 weeks proceed to permanent subcutaneous implantation of the device. The procedure for device placement is technically straightforward, and device-related complications are less frequent or significant relative to more invasive artificial sphincter devices discussed above. A multicenter US study assessing sacral nerve stimulation for FI is in progress.

Application of radiofrequency energy to the anal canal (the Secca procedure) improved fecal continence but not anal sphincter pressures in an uncontrolled study of 10 women with FI; the effects were maintained at 2 years thereafter [157]. Less optimistic results were reported in a larger multicenter trial [158].

Injectable sphincter bulking agents are effective for urinary incontinence [159]. Uncontrolled, predominantly small series have used autologous fat [160], collagen [161], implantable microballoons [162], carbon-coated beads [163], and silicone [164] to augment the pelvic barrier, with variable efficiency for FI. The largest study to date, using injectable silicone in 82 patients with severe FI and low anal resting pressure, was uncontrolled. Moreover, improvement in symptoms and resting anal pressures at up to 6 months after the procedure were modest, with limited follow-up thereafter [164]. The long-term efficacy and safety of these agents are unknown, and none are as yet approved by the FDA for use in FI.

Pruritus ani

Pruritus ani is an annoying itchy sensation of the anus and perianal skin that is often associated with burning and soreness. It may be transient or chronic, unrelenting, and difficult to treat. Periods of intense itching are characteristically most disturbing at night when daytime distractions are removed. It affects 1%–5% of the population, with a male-to-female predominance of 4:1 [165].

Pathogenesis

Pruritus ani may occur as a symptom of a specific disease affecting the perianal skin or, more commonly, as an idiopathic condition possibly related to residual fecal material (Table 66.4). A number of anorectal diseases, including fissures, fistulae, and hemorrhoids, make local hygiene especially difficult, and irritated macerated skin may develop. Pruritus, discomfort, and mucus drainage are more common in those suffering from hemorrhoids than in a control population, and often resolve with treatment of the hemorrhoids [166]. Anal malignancies, including Bowen disease, epidermoid cancers, and extramammary Paget disease, may rarely present as pruritus ani and should be considered even if symptoms have existed for years [167].

Candida albicans and dermatophytic infections appear as characteristic localized erythematous rashes but may also be cultured from the perianal area even if skin lesions are

Table 66.4 Causes of pruritus ani

Anorectal disorders
Diarrhea
Anal incontinence
Hemorrhoids
Fissures
Fistulae
Rectal prolapse
Malignancy: Bowen disease, epidermoid cancer, perianal Paget disease
Fungal: candidiasis, dermatophytes
Parasitic: pinworms, scabies
Venereal: herpes, gonococcus, syphilis, condylomata acuminata
Local irritants
Moisture: obesity, excessive perspiration
Soaps: hygiene products
Toilet paper: perfumed, dyed
Underwear: irritating fabrics, detergents
Anal creams, suppositories
Dietary: coffee, beer, acidic foods
Drugs: mineral oil, ascorbic acid, hydrocortisone sodium succinate, quinidine, colchicine
Dermatological diseases
Psoriasis
Atopic dermatitis
Seborrheic dermatitis

absent. *C. albicans* is more likely to be identified by random cultures, but dermatophyte infections tend to be associated with pruritus ani [168]. Pinworm (*Enterobius vermicularis*) causes pruritus ani that is characteristically nocturnal. Children are most commonly affected, but adults, especially those exposed to children, may occasionally become infected. Diagnosis is best made by applying adhesive cellophane tape to the perianal skin early in the morning in an effort to detect eggs. Scabies (*Sarcoptes scabiei)* and pubic lice (*Phthirus pubis*) can also cause pruritus ani. Itching in the genital region and identification of organisms or eggs on pubic hair lead to the proper diagnosis.

A controlled study failed to provide a bacteriological basis for this condition [169]. Sexually transmitted diseases associated with pruritus ani include herpes simplex, gonorrhea, syphilis, condyloma acuminatum, and molluscum contagiosum [170]. Dermatological conditions, such as psoriasis, eczema, and seborrheic dermatitis, must also be considered. One series of patients referred to a combined colorectal and dermatological clinic had a dermatosis, particularly psoriasis, as the most common cause of pruritus ani [171]. A variety of local irritants, allergens, and chemicals that contact the perianal skin may cause pruritus. Perfumes and dyes in toilet paper and soaps, personal hygiene products, irritating fabrics, laundry detergents, and even topical anal creams or suppositories are examples. Even certain chemotherapeutic agents have been implicated [172]. Clinical experience and elimination diets have implicated certain dietary products such as coffee, cola, beer, tomatoes, chocolate, tea, and citrus fruits, although the mechanism is unknown [173]. Food products such as lactose that cause diarrhea may lead to pruritus ani simply because of frequent fecal contamination of the perianal region.

Idiopathic pruritus ani is usually caused by a combination of perianal skin fecal contamination and trauma. Ambulatory monitoring of the anorectum has shown exaggerated transient internal sphincter relaxations, which likely predispose to subtle fecal leakage in idiopathic pruritus ani [174]. Acute diarrhea in an otherwise healthy person may irritate the perineum because of frequent wiping. Tiny amounts of feces repeatedly contaminate the perianal skin leading to further irritation. An itch–scratch cycle develops, which perpetuates skin trauma. Patients with chronic pruritus ani often suffer from frequent loose stools or some degree of fecal incontinence or seepage. The perianal area is repeatedly traumatized from vigorous wiping or scratching, and adequate healing can never occur. Pruritus is further exacerbated by inadequate perianal hygiene or excessive moisture caused by perspiration, airtight clothing, severe obesity, or a particularly deep-set anus.

Treatment

Most causes of pruritus ani can be successfully treated. Dermatological diseases and infectious causes should be treated in the usual manner. Anorectal disorders that impede good perianal hygiene, such as prolapsing internal hemorrhoids or anal fissures, should be corrected. Fecal leakage or incontinence must be aggressively managed to avoid soiling of perianal skin. For the same reason, frequent loose stools may be minimized with antidiarrheal agents if appropriate. Foods or beverages that produce diarrhea or pruritus in a particular individual should be discontinued. Blanket recommendations to discontinue or curtail coffee, beer, citrus fruits, and other foods reported to cause pruritus ani lack firm support, but elimination diets may be appropriate in particular cases.

The key to management of pruritus ani is to keep the anal area clean and dry while minimizing trauma caused by wiping and scratching [175]. The patient should be instructed gently to cleanse the anal skin with a premoistened pad or tissue after defecation. Witch hazel preparations or soothing lanolin-containing lotions always remove more residual feces than does dry wiping alone. The area should then be dried with a blow dryer or soft tissue using gentle dabbing without rubbing. Those with small amounts of fecal discharge are instructed to insert a thin cotton pledget into the anal canal, which should be changed frequently throughout the day. Excessive perspiration is corrected with application

of baby powder and avoidance of tight, nonporous clothing. Irritating fabrics, perfumed toilet paper, hygiene products, and soaps should be avoided. A 1% hydrocortisone cream may be applied sparingly twice daily during the acute phase of pruritus ani but should not be used for longer than 2 weeks to avoid skin atrophy. Applying a protective ointment (zinc oxide) over the antiinflammatory agent may facilitate healing. For severe nocturnal symptoms, a nighttime dose of a systemic antipruritic such as diphenhydramine is appropriate. Capsaicin cream was effective in 70% of patients with chronic pruritus ani in a randomized, double-blind, placebo-controlled cross-over study [176].

Proctalgia syndromes

Anorectal pain (proctalgia) is associated with a variety of organic conditions but also occurs in patients in whom organic conditions are not identified. The two common functional disorders – chronic proctalgia and proctalgia fugax – are distinguished by the duration and frequency of painful episodes and by the absence of physical findings in asymptomatic patients with proctalgia fugax [177]. Chronic proctalgia must also be distinguished from other disorders of chronic anorectal pain (i.e., coccygodynia, rare genetic syndromes of familial rectal pain, and other gynecological causes of chronic pain). In both entities, reports of effective therapy are largely anecdotal, and therapeutic modalities have not been examined rigorously with controlled trials.

Chronic proctalgia

The diagnosis of chronic proctalgia is made by the clinical history, physical examination, and exclusion of other disorders that can produce chronic anorectal pain. The pain is described as a dull or pressure-like discomfort in the rectum that lasts for several hours or longer. Both prolonged sitting and defecation may precipitate the pain; in addition, symptoms of difficult defecation or a sense of incomplete evacuation have been described [178,179]. A common clinical finding is palpable tenderness of overly contracted levator ani muscles as the examining finger moves from the coccyx posteriorly to the pubis anteriorly. The tenderness is often asymmetric and is most commonly found on the left [178]. An international committee has proposed diagnostic criteria, consisting of chronic or recurrent episodes of rectal pain or aching lasting for 20 min or longer for at least 3 months in the absence of other causes, such as ischemia, inflammatory bowel disease, cryptitis, intersphincteric abscess, anal fissure, hemorrhoids, and coccygodynia [179].

Chronic proctalgia may be further characterized as levator ani syndrome if posterior traction of the puborectalis muscle elicits tenderness, whereas if there is no tenderness, a diagnosis of "possible" levator syndrome or unspecified pain is considered. It has been estimated that 6%–7% of the general population have symptoms consistent with levator ani syndrome, but only 29% of affected individuals consult a physician [177].

Pathophysiology

Levator ani syndrome is hypothesized to result from overly contracted pelvic floor muscles. One study suggests that elevated anal canal pressures or EMG levels may constitute a useful quantitative sign for the diagnosis [180]. Grimaud and colleagues found elevated anal resting pressures in all 12 of their patients with levator ani syndrome [180]. Moreover, anal canal pressures normalized in association with pain relief after biofeedback therapy. These observations need to be confirmed in a controlled study with a larger number of patients. The pathophysiology of unspecified functional anorectal pain is poorly understood.

Treatment of chronic proctalgia

Treatments claimed to be effective are those that are directed towards reducing tension in the striated pelvic floor muscles. These include electrogalvanic stimulation [181], biofeedback training [182], muscle relaxants such as methocarbamol, diazepam, and cyclobenzaprine, digital massage of the levator ani muscles, and sitz baths [63]. A double-blind placebo-controlled study showed no efficacy of intrasphincteric injection of botulinum toxin A in levator ani syndrome [183].

Except as noted above, these therapeutic trials were uncontrolled, and patient selection criteria were variable. If circumstances require that treatment be undertaken, the only advice that can be offered is to do no harm, that is, to select a treatment, such as biofeedback, which has no significant adverse consequences. Surgical procedures such as division of the puborectalis muscle should be avoided because they do not correct the functional disorder and may lead to fecal incontinence [184].

Proctalgia fugax

Proctalgia fugax is characterized by sudden, episodic, severe pain in the rectal area that lasts for several seconds or minutes before disappearing completely. The pain has been described as aching, gnawing, cramping, or stabbing. In contrast to levator ani syndrome, patients who are asymptomatic during examination exhibit no characteristic physical findings. As a result, the diagnosis relies entirely on the clinical description, and the exclusion of other diseases that can produce proctalgia. In one survey, about 14% of a healthy population reported at least one episode of proctalgia fugax, and 5% reported having at least six episodes yearly. Less than 20% of affected individuals had sought medical attention [185].

Pathophysiology

The pathophysiology of the pain in proctalgia fugax is unknown. Early reports of anal sphincter spasm or contractions of the puborectalis and external anal sphincter

muscles [186] have never been substantiated. An autosomal dominant inherited myopathy of the IAS associated with both proctalgia fugax and constipation in members of two affected families has been described [187,188] but cannot be assumed to be the cause of most cases of proctalgia fugax. The potential role of psychological factors in proctalgia fugax is uncertain.

Treatment of proctalgia fugax

Treatment consists of an explanation of the disorder and reassurance, as episodes of pain in most patients are brief and infrequent. There have been scattered reports of benefits with clonidine [189], inhaled salbutamol [190], nitrates and diltiazem [191], and caudal epidural blocks [192].

The psychological findings in patients who consult for proctalgia include anxiety, depression, and a tendency towards hypochondriasis. When these symptoms are present, antidepressant or anxiolytic medications or behavioral therapies may be indicated. However, there are no studies on the outcome of such treatments for proctalgia fugax.

Coccygodynia

Coccygodynia refers to rectal pain that arises from the coccyx [193]. It is often described as an aching or gnawing that is sometimes sharp and may radiate into the buttocks. Coccygodynia may be caused by known causes (i.e., dislocation, fracture, arthritis, presumed injury during vaginal delivery), or it may be functional [177]. Pain may also be referred to the coccyx from the lumbosacral spine, sacrum, anus, rectum, pelvis, and genitourinary tract. The key to diagnosis is the reproduction of pain when the coccyx is manipulated; this distinguishes coccygodynia from other chronic proctalgia disorders. Lateral radiographs have shown two distinct findings in many patients with coccygodynia [194]. In the "luxation" group, posterior luxation occurs during sitting and disappears while the patient is standing. In the "hypermobility" group, the coccyx flexes abnormally while the patient is sitting.

Treatment

The initial treatment of coccygodynia is conservative and includes moist heat and analgesics. The painful coccyx should be protected by having the patient sit in a position that lessens pressure on the coccyx or on a doughnut-shaped pillow [195]. Local injection of corticosteroids into the area may benefit those who do not respond to conservative therapy. Manipulation of the coccyx under anesthesia to stretch the ligaments has been reported to be beneficial. Cryoanalgesia of the posterior rami of the lower sacral nerve roots and the coccygeal nerve has been advocated for patients who obtain temporary pain relief with local anesthetic injections [196]. Rarely, coccygectomy may be performed for severe and unresponsive organic coccygodynia [195].

Rectal foreign bodies and trauma

The insertion and incarceration of foreign objects into the anus and rectum is a well-described phenomenon and can no longer be considered rare [197,198]. These objects are inserted for purposes of medical treatment, concealment, assault, or most commonly, eroticism. In an attempt to cope with an embarrassing situation, patients may claim the object was inserted to obtain relief from a particular discomfort or symptom. Frequently, the patient may complain of pain or bleeding without admitting to a foreign body insertion [199]. A directed interview and careful abdominal and rectal examination are necessary to identify the foreign body and the potential risk of rectal trauma. Anteroposterior and lateral radiographs should be obtained to determine the object's outline and location and to detect pneumoperitoneum if present. Less commonly, a patient may unwittingly swallow a toothpick or piece of bone that later impacts in the anal canal and may mimic an abscess or fissure.

Management involves the safe retrieval of the object. Many can be removed transanally without resorting to surgery. Even if the object is easily palpable, removal under direct vision is the best way to avoid iatrogenic injury [200]. The location of foreign bodies may be classified as "low" if in the rectal ampulla or "high" if at or proximal to the rectosigmoid junction [200]. Many small, low-lying objects can be retrieved transanally using an operative anoscope. Removal of larger objects, such as vibrators or rubber phalluses, may require regional anesthesia, anal dilation, and a grasping forceps. Large, bulky objects, such as glass bottles and lightbulbs, require special care. After adequate anesthesia, several Foley catheters are inserted past the object. Air insufflation through the catheters relieves the proximal vacuum effect that may occur during attempted withdrawal. Gentle manipulation coupled with slow traction using the inflated Foley balloons successfully extricates the bulky object in most cases. An obstetrical vacuum extractor has also been used to remove a glass foreign body. If a glass object is broken accidentally during attempted removal, laparotomy is required.

High-lying foreign bodies are best managed using spinal anesthesia and the lithotomy position. By palpating the abdomen, the object may be pushed distally and then simultaneously grasped with forceps through the sigmoidoscope to coax it into the rectal vault, from which it may be removed. If the object cannot be delivered to within reach of the rigid sigmoidoscope manually or after 12 h of observation, laparoscopic assistance can be used to push the object distally to assist with removal [201]. In a large review, 76% of patients with objects in the rectum had a successful bedside extraction, whereas 55% of patients with foreign objects in the sigmoid colon required laparotomy [200]. Proctosigmoidoscopy should be performed after all foreign body retrievals to rule

out retained objects, lacerations, hematomas, and perforations. If peritonitis develops, urgent laparotomy is required.

Other causes of rectal trauma include penetrating injuries (usually gunshot wounds), blunt trauma (motor vehicle accidents), impalement injuries (criminal assaults), homosexual activities (fist fornication), and iatrogenic injuries (endoscopy, enemas, surgical procedures) [202]. Surgical management of major rectal trauma usually includes a diverting colostomy, presacral drain placement, distal rectal irrigation, and maximum preservation of sphincter musculature [203].

Anal intraepithelial neoplasia

Anal intraepithelial neoplasia (AIN) is believed to be a precursor of anal squamous cell cancer. Its incidence is rising in high-risk groups, particularly those infected with the human immunodeficiency virus (HIV). This condition is subclassified into low-grade anal squamous intraepithelial lesion (LSIL), equivalent to AIN grade 1, and high-grade anal squamous intraepithelial lesion (HSIL), equivalent to AIN grades 2 and 3. The term Bowen disease of the anus is sometimes used to denote AIN grade 3.

Etiology

These tumors are strongly associated with receptive anal intercourse in homosexual men and with sexually transmitted diseases, especially genital warts, in both genders [204]. Anal cancer shares several similarities with cervical cancer. First, the incidence of anal cancer in men who practice anoreceptive intercourse is 35 per 100 000, which is higher than the incidence of cervical cancer of 8 per 100 000 [204,205]. Second, human papillomavirus infection, particularly type 16, plays a causal role in both cancers [206,207]. Third, both originate from a precursor lesion (i.e., squamous intraepithelial lesions). Smoking, HIV infection, multiple sexual partners, cervical neoplasia, and immunosuppression after organ transplantation are other important risk factors [208].

Palefsky et al. characterized the natural history of AIN in 346 HIV-positive and 262 HIV-negative men who had sex with men [209]. Among HIV-positive men who were normal at baseline, 52% progressed to anal squamous intraepithelial lesions (ASIL) within 2 years compared with 17% of HIV-negative men. An even higher proportion of HIV-positive and HIV-negative men (70% and 31%, respectively) progressed to ASIL when diagnosed with atypical squamous cells of uncertain significance at baseline. A high proportion of those with LSIL at baseline progressed to HSIL (62% and 36%, respectively.) Other studies have shown that AIN grade 2 or 3 rarely regresses, even in HIV-negative individuals [210], and can progress to invasive cancer. In two studies, approximately 5% of AIN grade 3 lesions became malignant over two decades [210–212]. Anal cytology screening may be cost-effective in homosexual and bisexual men [213].

Clinical features, diagnosis, and management

Anal intraepithelial neoplasia is often subclinical and diagnosed when high-risk patients are screened with cytology or anal colposcopy [214]. The AIN lesions do not have a specific appearance; suspicious areas are raised, scaly, white, erythematous, pigmented, or fissured. Anal cytology has a 92% sensitivity for distinguishing benign from malignant lesions. However, cytology was only 50% specific for distinguishing benign from malignant lesions. Although colposcopy is useful for detecting AIN, colposcopy and histopathology are necessary to define the site and extent of AIN. Because the natural history and malignant potential of AIN are uncertain and because an effective therapeutic option is not available, management is not standardized. Patients with AIN should be monitored, perhaps every 12 months for HIV-negative patients with AIN grades 1 or 2, and every 4–6 months for HIV-positive patients with AIN grades 1 or 2, as also for patients with AIN grade 3 [214]. All suspicious lesions should be biopsied or excised. Unfortunately, HIV-positive patients frequently have persistent or recurrent high-grade AIN after treatment of the initial lesion. The roles of photodynamic therapy and argon laser therapy require further investigation [214].

Anal carcinoma

Anal carcinomas comprise 1%–2% of all colonic cancers. A variety of histological types have been described, including: squamous cell (70%–80%); basaloid, also known as transitional cell or cloacogenic (20%–30%); mucoepidermoid (1%–5%); and small cell anaplastic type (< 5%) [215]. All can be broadly classified as epidermoid carcinomas for purposes of clinical discussion. The mean age at presentation of patients with anal cancer is approximately 60 years [216]. Perianal and rectal carcinomas are more common in men, but anal canal tumors are nearly twice as common in women [216].

Clinical manifestations

Bleeding, pain, pruritus, and discharge are the most common symptoms of anal cancer. These relatively nonspecific symptoms are often attributed to common benign anorectal disorders, as previously discussed. Consequently, the tumor is often diagnosed when patients develop additional symptoms such as incontinence, change in bowel habits, pelvic pain, or a rectovaginal or rectovesical fistula, which suggest an advanced malignancy. The tumor may be discovered incidentally in specimens obtained for benign anorectal disease [217,218]. However, benign anal lesions do not appear to cause anal cancer [219]. At presentation, 15%–30% of patients have metastases to pelvic or inguinal lymph nodes, and 10% have distant spread to the liver or lungs [215]. Rarely, a palpable metastatic inguinal lymph node is the sole

presenting manifestation. High-grade dysplasia identified by screening cytology must be confirmed by biopsy and may be present before visible lesions exist [220].

The physical examination and clinical investigations are directed toward establishing the diagnosis and staging. For small lesions, it is important to ascertain the site of origin (i.e., the anal canal or anal margin). For large lesions that overlap the canal and the margin, this distinction may not be possible and is probably less important because therapy is guided by sensitivity to radiotherapy and chemotherapy as determined by histological type. The assessment, if necessary under general anesthesia, includes digital examination to evaluate the size and mobility of the mass, invasion of surrounding structures, and the presence of pararectal or inguinal lymph nodes; biopsies are also obtained. A colonoscopy is recommended to exclude colorectal carcinoma. Paraaortic lymph nodes can be identified by a CT scan of the abdomen and pelvis whereas pararectal nodes can be biopsied by endoanal ultrasound. Lesions originating from the anal canal tend to be undifferentiated and more aggressive, in contrast to those arising from the anal margin [221]. A poor prognosis is portended by squamous cell tumors greater than 2 cm in size (especially those > 5 cm), basaloid or anaplastic carcinomas, sphincter muscle invasion, or spread to regional pelvic or inguinal lymph nodes [215].

Treatment

Local excision is the primary modality for carcinoma at the anal margin. In the largest series, the 5-year survival was 65% [222]. Large or infiltrating lesions require an abdominoperineal resection for radical excision of structures, including the sphincters, levator muscles, and rectum. Prophylactic inguinal lymph node resection is not indicated. Among 11 patients treated by abdominoperineal resection with curative intent, the 5-year survival rate was only 36%. Another study reported a recurrence rate of 63% after excision of lesions at the anal margin [223]. However, recurrent lesions often respond to further local treatment [224].

Chemoradiotherapy has replaced surgery as the primary therapeutic modality for anal canal carcinoma [225–227]. Anal squamous cell carcinoma (SCC) is more radiosensitive than SCC arising in other locations. Chemotherapy enhances the effect of radiotherapy, improves tumor control, and minimizes severe complications. Even large, locally advanced tumors are amenable to initial chemoradiotherapy. Prospective randomized or multicenter trials demonstrate that compared with radiotherapy alone, chemoradiotherapy with 5-fluorouracil (5-FU) and mitomycin-C (MMC) provides superior local control, colostomy-free rate, progression-free survival, and cancer-free survival without significantly increasing late complications and non-cancer-related deaths. In large studies, 5-year disease-free survival rates after combined therapy range from 60% to 86%. The addition of MMC to RT and 5-FU improves local control, colostomy-free rate, tumor progression, and cancer-free survival. The incidence of acute hematological toxicity is greater with combined chemoradiotherapy using 5-FU and MMC than with radiotherapy (RT) plus 5-FU. Anal cancers regress slowly after chemoradiotherapy. Six months after therapy, a large part of the residual mass contains nonmalignant tissue. Frequent, multiple biopsies should be performed to identify residual malignant tissue, which is eminently curable with radical surgery.

Nonepidermoid anal malignancies

Adenocarcinomas may arise in the distal rectum and invade the anal canal. Rarely, adenocarcinomas may arise in the anal canal, either from the anal glands or from malignant transformation of a long-standing fistula-in-ano, such as in Crohn's disease [216]. Despite radical abdominoperineal resection, recurrences are typical.

Paget disease is an extremely rare lesion of the perianal skin. Older patients (mean age 60s) commonly complain of pruritus, occasionally with bleeding, a lump, soiling, or a change in bowel habits. Examination reveals an erythematous, well-demarcated eczematoid plaque with well-demarcated edges, and occasionally with ulceration. The characteristic Paget cells are large, rounded epithelial cells of apocrine origin with pale cytoplasm and a large nucleus. The presence or absence of apocrine markers on staining is used to differentiate between low-grade and high-grade malignant lesions respectively. The workup for an associated malignancy includes at least a colonoscopy. Treatment is by surgical excision guided by the extent of disease; the role of chemoradiation therapy is unclear [228].

Melanomas account for 1% of all anal tumors and most commonly present with rectal bleeding. The lesion often mimics a thrombosed external hemorrhoid. However, up to 25% are amelanotic. These tumors tend to metastasize early with 5-year survival rates of only 15%–20% [229]. Radical resection offers no clear advantage over wide local excision [230,231].

Basal cell carcinoma of the perianal skin is a rare lesion that produces rolled skin edges with central ulceration. The prognosis is good after adequate local excision or radiotherapy [232].

Miscellaneous conditions

Pilonidal disease

This is a common skin lesion of the gluteal cleft seen most frequently in young men, who complain of recurrent drainage, swelling, or pain [233]. Although once thought to be congenital, it is an acquired disorder in which vacuum and pulling forces in the natal cleft are thought to draw hair into the follicles, which in turn become blocked by the hair and

keratin. Subsequently, a foreign body reaction, abscess, and rupture of follicles begin the process by which pilonidal sinus disease forms [234].

The first line of treatment is incision and drainage of any abscesses followed by routine wound care until healing is complete. This is followed by regular and meticulous shaving and hair removal from the midline area of involvement until the wound has closed [235]. Conservative treatment alone is effective if patients present with pain and occasional drainage but no infections or abscess. The use of antibiotics and drains has not been shown to be helpful. If conservative measures fail, multiple surgical options have been reported, none of which has been demonstrated to be completely definitive [236]. One study reported that rhomboid excision and Limberg flap closure was superior to simple excision and primary closure [237]. Other treatments include the addition of a gentamycin collagen fleece to aid healing after primary closure [238] and fibrin tissue glue injection after curettage [239].

Hidradenitis suppurativa

This is a chronic suppurative condition of the follicular epithelium most often involving the axillary and inguinoperineal skin regions. Hormonal influences may be significant as the disease is not seen before adolescence and rarely begins after middle age [240]. Genitofemoral and perineal involvement are seen in nearly one-third of those with the disease, especially in women. Recognized risk factors are female gender, obesity, and acne, although perspiration and mechanical trauma to the skin and hair of the anogenital region may also predispose to perianal hidradenitis [240].

Warm wet compresses, systemic antibiotics, and topical antiseptics are appropriate for early disease. Surgical treatment is the most effective treatment modality for those who do not respond to conservative therapy [240]. Infliximab, a chimeric monoclonal anti-tumor necrosis factor (TNF) antibody, has been reported to be effective in several patients [241]. Other treatments reported to have had some success are combined antiandrogen and antiestrogen therapy and the 5-alpha reductase inhibitor, finasteride [240].

Cross-sectional imaging techniques have greatly increased the understanding of pancreatic anatomy, and the ability to manipulate the pancreas surgically, endoscopically, and percutaneously has made it necessary for a wide variety of physicians to become familiar with pancreatic anatomical variations. The anatomy of the pancreas has been described in many standard texts, but the functional and therapeutic implications of its anatomical relations often are underemphasized.

Diseases of the pancreas are often more difficult to manage medically or surgically than those of other abdominal viscera. The pancreas lies hidden in the deeper recesses of the retroperitoneal space of the upper abdomen, is largely protected by the lower rib cage anteriorly, and is almost completely covered by the stomach, transverse colon, and transverse mesocolon. At laparotomy, the pancreas cannot be properly visualized or palpated without extensive dissection, mobilization, and retraction.

The central position of the pancreas provides for lymphatic drainage along several major routes, namely, the splenic, hepatic, and superior mesenteric nodal systems as well as the aortocaval and other posterior abdominal wall lymphatics. Moreover, the intimate anatomical association of the pancreas with vital major vessels of the epigastrium at once limits the extent of any surgical procedure and also dictates what must be removed. Thus, when a tumor spreads a short distance to involve the superior mesenteric vein, the portal vein, or the celiac axis, it usually becomes incurable. Similarly, if the gland is removed in radical fashion, the need to excise the vessels and lymph nodes associated with it frequently makes necessary the removal of the duodenum, gallbladder, distal bile duct, spleen, upper jejunum, and part of the stomach. Finally, the vascular nature of the pancreas and the adjacent organs makes it easy to understand why the most common intraoperative and postoperative complication of pancreatic resection is hemorrhage.

Textbook of Gastroenterology, Fifth Edition Edited by Tadataka Yamada

Embryological development

The pancreas develops from two primordial outpouchings of the duodenum and is first apparent at 4 weeks of gestation. The dorsal pancreatic bud grows more rapidly than the ventral pancreas and by the sixth week extends into the dorsal mesentery. The ventral pancreas remains smaller and is carried away from the duodenum by the development of the hepatic rudiment into the biliary system. Investigations have shown that sonic hedgehog (SHH) expression in the embryonic foregut suppresses pancreatic differentiation of the stomach and duodenum. In the dorsal bud, signals from overlying notochord and dorsal aorta result in downregulation of SHH expression and development of pancreatic tissue. The ventral endoderm closer to the developing major papilla differentiates into pancreatic tissue whereas signals from the septum transversum lead to upregulation of SHH in the nascent hepatic bud [1]. Differential growth of the duodenum and axial rotation of the gut result in the dorsal pancreas being carried to the left and the ventral pancreas being carried to the right of the duodenum (Fig. 67.1). Migration of the distal common bile duct behind and to the left of the duodenum causes the ventral pancreas to lie below the dorsal pancreas, forming the uncinate process of the pancreas. The common bile duct lies posterior to the dorsal pancreatic duct. Fusion of the two parts of the pancreas occurs during the seventh week of gestation. Fusion of the ventral duct with the dorsal duct results in the formation of the main pancreatic duct. The proximal end of the dorsal pancreatic duct usually does not communicate with the main duct and forms the accessory pancreatic duct.

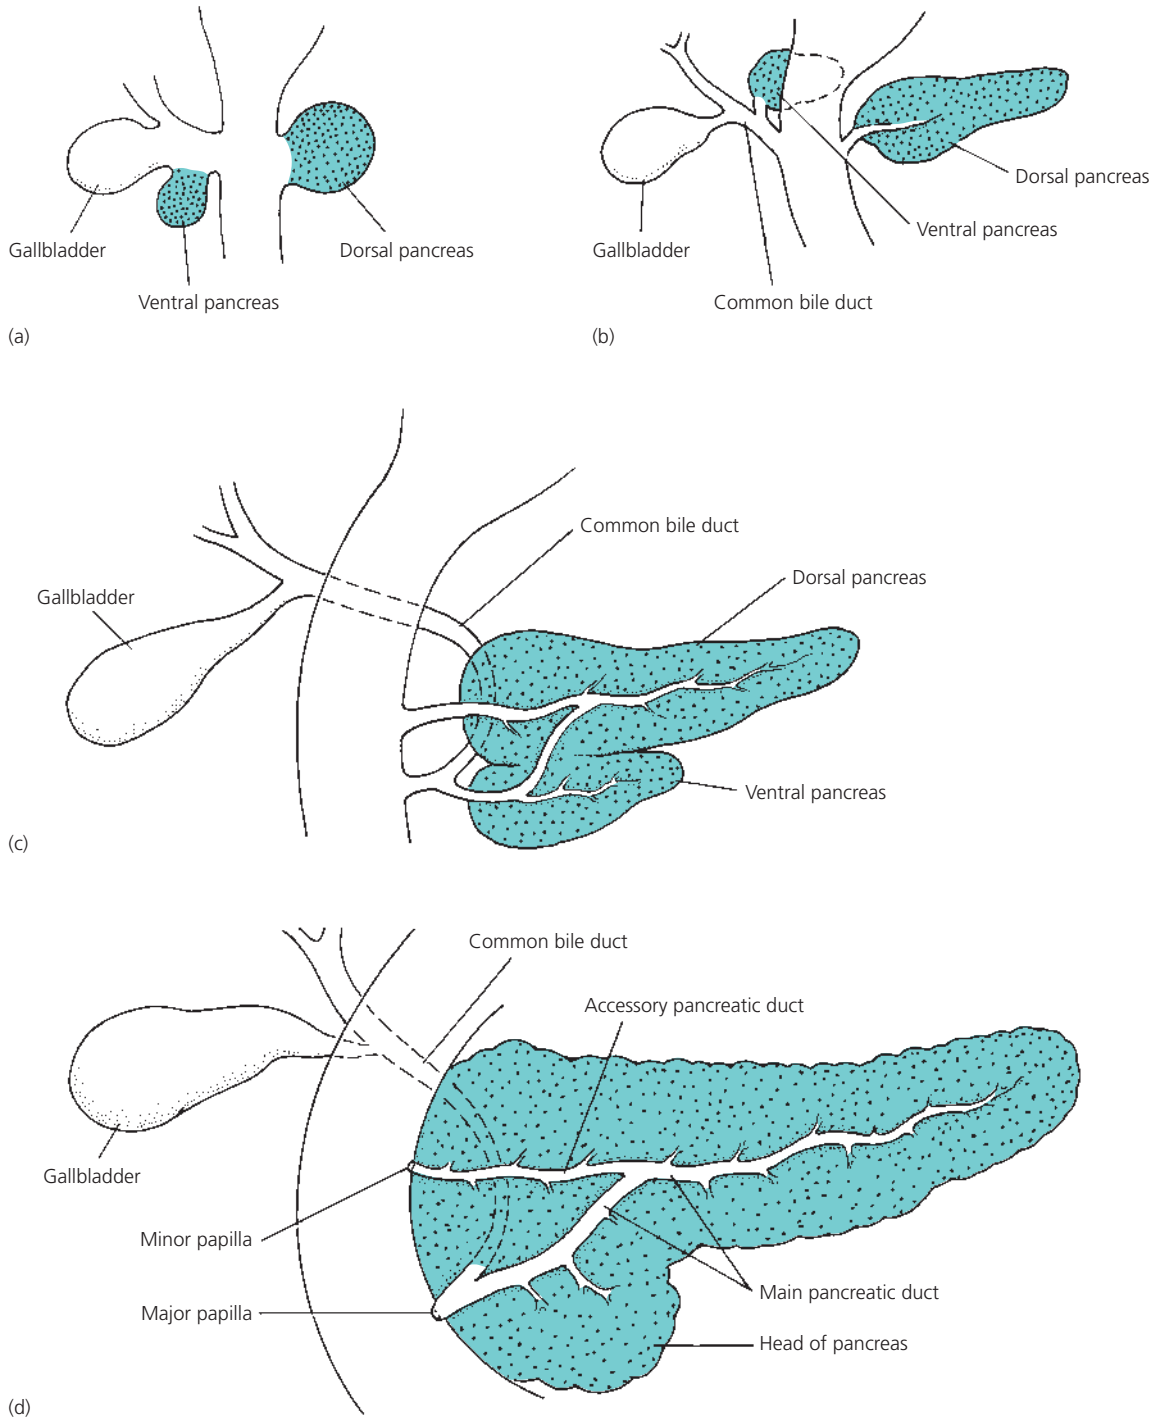

Figure 67.1 Embryological development of the pancreas. The various stages of intrauterine pancreatic growth are shown at 4 weeks **(a)**, 6 weeks **(b)**, 7 weeks **(c)**, and birth **(d)**. Adapted from Arey LB. Developmental Anatomy, 7th edn. Philadelphia: WB Saunders, 1974:259, with permission from Elsevier.

The pancreatic acini and the first zymogen granules appear at 12 weeks of gestation. Groups of endocrine cells develop from multipotential stem cells in the ductular epithelium (nesidioblasts) at 9 weeks of gestation. Discrete islets of Langerhans cells can be identified at 12 weeks. Most of the islet cells develop within the tail of the pancreas and the dorsal pancreas. The first cells to produce granules are the alpha cells, soon followed by the beta and delta cells. Complete maturation of the pancreatic gland does not occur until sometime after the end of gestation. The smooth muscle of

the sphincter of Oddi develops independently of the duodenal musculature, and only later does it become incorporated into the duodenal wall.

Most evidence indicates that islet cells arise from stem cells that appear in pancreatic ducts during the third month of gestation. Insulin-containing granules may be demonstrated immunocytochemically by the end of the third month. Islet cells migrate away from the ducts in which they arise and move into the interlobular connective tissue. Mature islet morphology is established before birth.

Gross anatomy

The pancreas is a soft, flattened, elongated gland, 12–20 cm long in the adult, that lies behind the peritoneum of the posterior abdominal wall and is obliquely rather than transversely oriented (Fig. 67.2; see also Fig. 67.1). The pancreas has a lobular structure and, although totally invested in fine connective tissue, does not have a true fibrous capsule. The adult gland weighs 85–95 g. Because of its oblique orientation, a transverse section or computed tomography (CT) scan normally does not pass through the entire length of the gland. The head of the pancreas is on the right side and lies within the C-shaped concavity of the duodenum at the level of the body of L2. The tail of the gland is to the left, lies between the two layers of peritoneum that form the lienorenal ligament, and is located at the level of the body of L1. The first portion of the duodenum is suspended in front of the head of the gland. The lesser curvature of the second part of the duodenum and the upper aspect of the third part of the duodenum intimately invest the head of the pancreas. Superiorly, the head is related to the gastroepiploic foramen and the structures that form the contents of the free border of the lesser omentum. Anteriorly, the first portion of the duodenum covers the superior part of the pancreatic head, and below this the right side of the transverse mesocolon is attached transversely. Posteriorly, the head of the pancreas contacts the right renal hilum, both renal veins, the inferior vena cava, and the termination of the right gonadal vein as well as the right side of the aorta [2].

The distal end of the common bile duct passes behind the upper border of the head of the pancreas. The bile duct grooves the posterior aspect of the head of the gland before passing through the substance of the head to reach the duodenal papilla of Vater. From the posterior aspect of the head, a tongue of pancreatic tissue of variable size, the uncinate process, extends to the left to occupy the concavity formed by the third and fourth parts of the duodenum. The uncinate process lies anterior to the inferior vena cava and aorta and is covered superiorly and anteriorly by the superior mesenteric vessels as they emerge below the neck of the pancreas.

From the head of the pancreas, a constricted part of the gland, the neck of the gland, extends toward the left. It is 3–4 cm wide and joins the head of the gland to the body of the gland on the left. The pancreatic neck lies behind the posterior peritoneum of the lesser sac, and its inferior border is covered by the attachments of the transverse mesocolon and the root of the small bowel mesentery. The neck of the pancreas lies anterior to and is closely related to the confluence of the superior mesenteric and splenic veins, which form the lowest part of the portal vein.

In front of the aorta in the midline, the body of the pancreas continues its retroperitoneal course toward the left side,

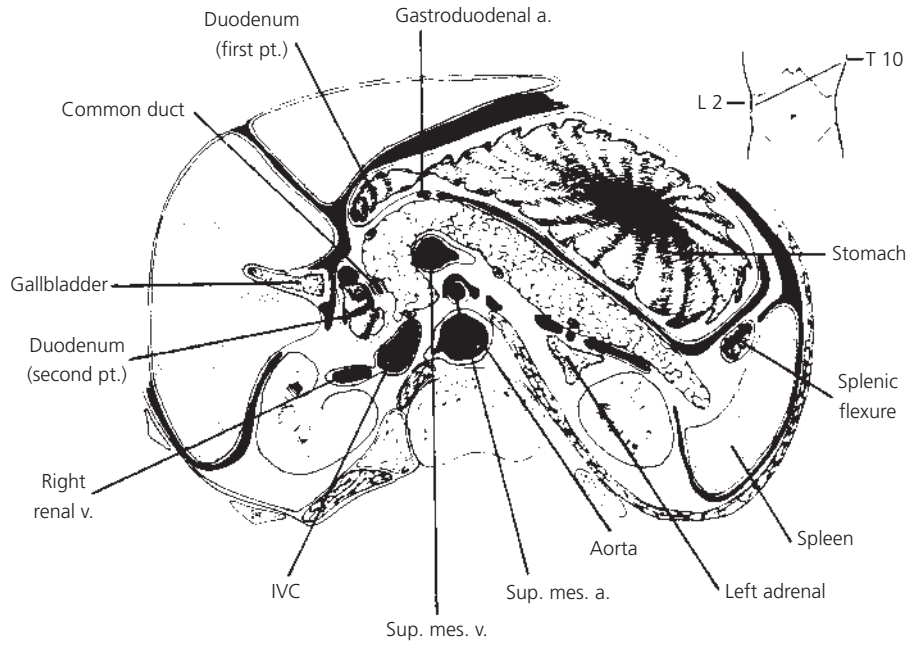

Figure 67.2 Oblique transverse cross-section of the upper abdomen viewed from below. The section passes through the long axis of the pancreas at approximately the level indicated in the inset. The disposition and relations of structures shown approximate those seen on oblique transverse ultrasonic scanning. a., aorta; mes., mesenteric; sup., superior; v., vein.

held securely against the aorta and the posterior parietes by the posterior peritoneum of the lesser sac. The antrum and the body of the stomach contact the body of the pancreas anteriorly. Posteriorly, the left renal vein, passing between the aorta and the pancreas, is separated by the latter from the first part of the superior mesenteric artery. At a slightly higher level, elements of the celiac and superior mesenteric plexus ramify between the pancreas and the aorta. The midline part of the body of the pancreas is pushed anteriorly by the bodies of L1 and L2 and, therefore, lies closest to the anterior abdominal wall. Because of its prominence and fixity in this region, this area of the pancreas is most vulnerable to blunt abdominal injuries. In addition, a tumor in this region may be palpated as a mass that does not move with respiration and that strongly transmits the aortic pulsation. The celiac axis, surrounded by the celiac plexus, divides into its major branches between the superior border of the body of the pancreas and the crura of the diaphragm.

The body of the pancreas passes laterally, posteriorly, and slightly cephalad behind the posterior peritoneum of the lesser sac and merges imperceptibly with the tail of the gland. The exact junction of the body and tail is not discernible anatomically. The posterior relationships of the body and tail of the pancreas include the posterior attachment of the left crus of the diaphragm, the left suprarenal gland, the upper pole of the left kidney, and hilum of the spleen. The splenic vein above and the left renal vein below lie close to one another behind the body and tail of the gland.

At the upper border of the body and tail of the pancreas, the splenic artery courses to the left from its origin at the celiac axis. The transverse mesocolon is attached to the anterior part of the lower border of the gland. The splenocolic ligament attaches the splenic flexure of the colon to the hilum of the spleen and brings it adjacent to the tail of the pancreas.

The shape and disposition of the pancreas varies, as demonstrated by pancreatography. In 57% of people, the bulk of the head of the gland is to the right of the spinal column. In about 38% of cases, it lies directly over the spine, but only rarely (5%) does the head of the pancreas lie to the left of the spine. There is a tendency in elderly people for the pancreas to be ptotic. The duodenal opening of the main pancreatic duct lies at the level of L2–L4 in 92% of cases, but rarely it has been described at a lower level.

Surgical exposure

Although the pancreas is located retroperitoneally, it must be approached by way of an anterior laparotomy incision. Little of the gland can be seen or palpated at laparotomy without dissection. In a thin patient, small areas of the head may be seen directly behind the peritoneum of the supracolic and right infracolic compartments, and the inferior border of the body and tail may be seen from the left infracolic compartment at the root of the transverse mesocolon. These limited views, however, usually are obscured by omental, mesocolic, and retroperitoneal fat. The neck of the pancreas may be felt from above by a finger passed through the gastroepiploic foramen of Winslow.

The head of the pancreas may be inspected and palpated more closely by performing two maneuvers [3]. First, the hepatic flexure of the colon is mobilized downward and medially, dividing the attachments of the transverse colon to the front of the duodenum and pancreatic head as far as the origin of the middle colic vessels. In addition, the attachments of the right side of the greater omentum to the transverse colon are divided. Thus, the lesser sac can be widely exposed on the right side of the middle colic vessels. Second, the peritoneum lateral to the second part of the duodenum is incised, and the duodenum and pancreatic head may be elevated and swept to the left by blunt dissection, exposing the right renal vein, the inferior vena cava, the right gonadal vein, the origin of the left renal vein, and the retroduodenal and retropancreatic portions of the distal common bile duct. After this mobilization (Kocher maneuver), the head of the pancreas may be palpated anteroposteriorly between the thumb and fingers. The mesenteric vessels are obscured from view by the uncinate process.

Limited sight of the superior part of the body of the pancreas may be obtained by opening an avascular part of the lesser (gastrohepatic) omentum and retracting the lesser curvature of the stomach inferiorly. This maneuver also brings the celiac axis into view. A much better sight of the body of the pancreas may be obtained by widely opening the lesser sac, which can be achieved by dividing the gastrocolic omentum at its attachment to the transverse colon. Extending this opening to the right into the subpyloric region allows visualization of the anterior aspect of the head and neck of the pancreas, especially if the right gastroepiploic vessels are ligated and divided. Extending the opening to the left and dividing the short gastric (gastrosplenic) vessels in the gastrosplenic ligament superiorly and the relatively vascular splenocolic ligament inferiorly will give complete visualization of the anterior surface of the body and tail of the pancreas. The spleen, splenic vessels, and tail of the pancreas may be mobilized medially and anteriorly en bloc, allowing inspection of the posterior aspect of the tail and body of the gland. All these surgical maneuvers may be carried out quickly and safely with little risk of damage to vital structures or troublesome bleeding. By this means, all except the region of the neck and uncinate process of the pancreas may be evaluated fully.

Arterial blood supply

The pancreas derives its blood supply from the celiac axis and the superior mesenteric artery (Fig. 67.3). These major

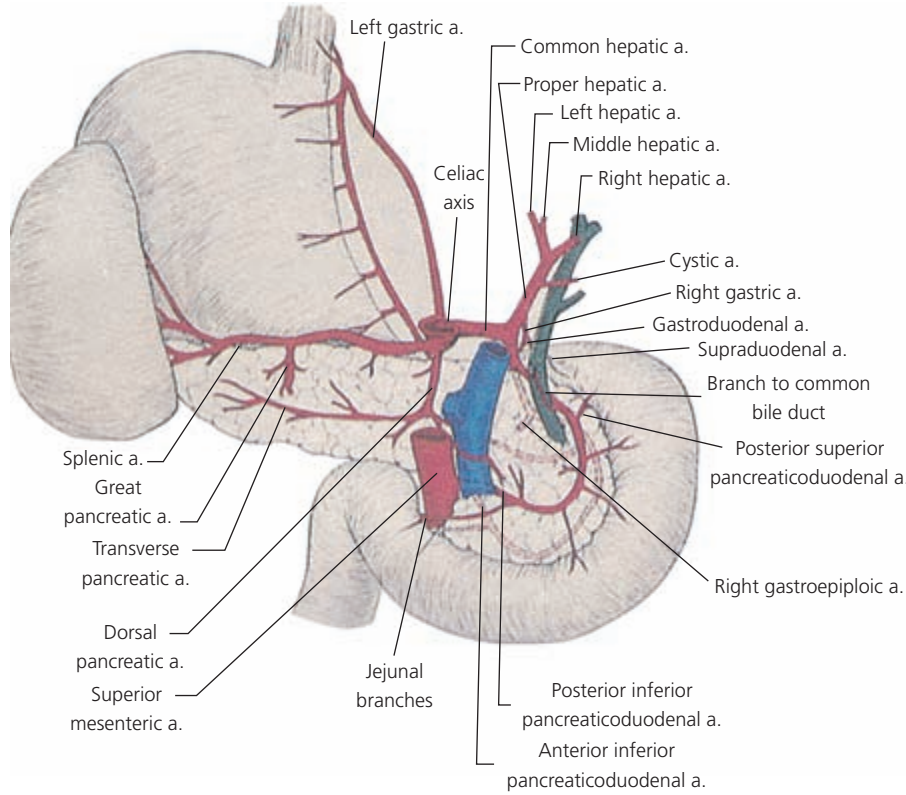

Figure 67.3 Blood supply of the pancreas. The pancreas, duodenum, stomach, and spleen are viewed from their posterior aspects. a., aorta.

vessels and their branches also provide the blood supply to other vital organs adjacent to the pancreas.

Typically (in 90% of people), the celiac axis divides into the common hepatic, the splenic, and the left gastric arteries. The common hepatic artery passes to the right, anterior to the portal vein, to reach the free border of the lesser omentum and usually lies to the left of the common bile duct. After giving off the gastroduodenal artery, the hepatic artery turns upward toward the porta hepatis and divides into the left and right hepatic arteries. The middle hepatic artery, supplying the caudate lobe of the liver, is usually a branch of one of these two vessels. This arrangement of the hepatic arterial blood supply, however, occurs in only 55% of people. Replaced or accessory hepatic arteries are frequent, occurring in as many as 30% of people. The most frequent variation from normal is the right hepatic artery branching off from the superior mesenteric artery and coursing behind the uncinate process and the head of the pancreas to reach the free border of the lesser omentum [4].

The gastroduodenal artery usually originates from the hepatic artery. The gastroduodenal artery courses from its origin behind the first part of the duodenum and, after giving off the posterior superior pancreaticoduodenal artery, lies on the anterior surface of the head of the pancreas. At the lower border of the first part of the duodenum, it branches into the right gastroepiploic artery and the anterior superior pancreaticoduodenal artery.

For the most part, the head of the pancreas and the duodenum have a common blood supply: the anterior and posterior pancreaticoduodenal arcades. The anterior arcade gives off the only arteries that enter the head of the gland from its anterior aspect. This arcade is formed by the anastomosis of the anterior superior pancreaticoduodenal artery, which is a terminal branch of the gastroduodenal artery, and the anterior inferior pancreaticoduodenal artery, which is usually a branch of a common inferior pancreaticoduodenal artery, arising from the superior mesenteric artery.

The posterior pancreaticoduodenal arcade is formed by the anastomosis of the posterior superior pancreaticoduodenal artery, usually a branch of the gastroduodenal artery, and the posterior inferior pancreaticoduodenal artery, which arises in a way analogous to the anterior pancreaticoduodenal artery. Of surgical importance is the relation of the posterior superior pancreaticoduodenal artery to the common bile duct. Typically, this vessel arises from the gastroduodenal artery and passes to the right, anterior to the common bile duct, contributing the major source of the structure's blood supply. The supraduodenal portion of the common bile duct also may be crossed anteriorly by the right hepatic artery, the right gastric artery, and the supraduodenal artery, making mobilization of the lower end of the common bile duct more difficult.

Because of the shared blood supply of the duodenum and pancreatic head, extensive interference with the pancreaticoduodenal arcades in the course of a 95% pancreatectomy

may compromise the blood supply of the duodenum [5]. In addition, because the duodenojejunal flexure and the first part of the jejunum may derive their blood supply from branches of the inferior pancreaticoduodenal artery or the pancreaticoduodenal arcades, ligation of these vessels in the course of a resection may render the proximal jejunum ischemic.

The body and tail of the gland derive their blood supply chiefly from branches of the splenic artery. This vessel, the largest branch of the celiac axis (5–11 mm in diameter), courses laterally at the upper border of the pancreas; its characteristic marked tortuosity appears to be related to age: It is often absent in infants and is most marked in the elderly. The splenic artery gives multiple side branches to supply the neck, body, and tail of the pancreas. The termination of the splenic artery passes between the layers of the lienorenal ligament and, at the hilum of the spleen, four or five branches enter the splenic hilum separately.

Venous drainage

The general pattern of veins draining the pancreas is the same as that of the arterial blood supply (Fig. 67.4). Blood from the pancreas drains ultimately into the portal vein, which is formed by the junction of the superior mesenteric vein and splenic vein behind the neck of the gland. The close relationship of the portal and superior mesenteric veins to the head, neck, and uncinate process of the pancreas is of vital surgical importance; in determining the resectability of a pancreatic lesion, a key step is assessment of involvement of these veins. The portal vein originates from behind the neck of the pancreas as a continuation of the superior mesenteric vein after it becomes confluent with the splenic vein. The portal vein passes upward to the right to gain access to the free border of the lesser omentum, where it lies posterior to the hepatic artery and the common bile duct. At the porta hepatis, it divides into a short, broad right branch and a longer, narrower left branch. In adults, the portal vein is about 8–10 cm long and 8–14 mm wide. Its average length is about 8.4 cm [6].

The splenic vein originates at the hilum of the spleen by the confluence of five or six tributaries draining the spleen. It receives the basal brevia (short gastric veins) and left gastroepiploic veins at the hilum. It passes through the lienorenal ligament behind the tail of the pancreas and below the splenic artery and is the large, straight vein that courses to the right in contact with the posterior surface of the pancreas. It receives many tributaries from the tail, body, and neck of the gland.

Below the pancreas, the ileocolic vein passes directly, and usually without tributaries, from the ileocecal region to join the right side of the superior mesenteric vein in the midline just above the inferior border of the third part of the duodenum. At about the same level on the left side, the superior mesenteric vein is joined by the jejunointermediate vein. The

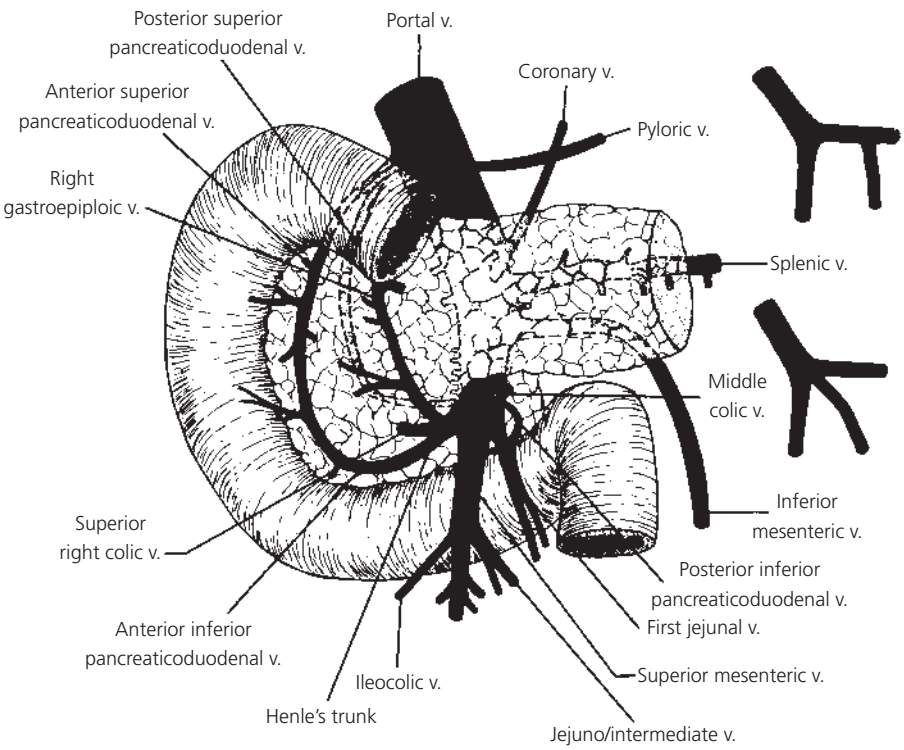

Figure 67.4 Venous drainage of the pancreas. The pancreas and duodenum are viewed from their anterior aspects. **Insets**: normal variations in the termination of the inferior mesenteric vein. v., vein.

confluence of these three veins forms the lower limit of what has been termed the surgical trunk of the superior mesenteric vein. Above this point, about two-thirds of the superior mesenteric vein lies below the inferior border of the neck of the pancreas, with the remaining one-third retropancreatic. The superior jejunal vein joins the left side of the superior mesenteric vein. The middle colic vein usually joins the superior mesenteric vein immediately below the inferior border of the pancreatic neck.

The inferior mesenteric vein typically joins the splenic vein vertically behind the body of the pancreas. The latter passes horizontally and combines with the superior mesenteric vein at a right angle to form the portal vein, which turns obliquely to the right to pass into the free edge of the lesser omentum. Small veins draining the head of the pancreas pass directly into the portal vein. Similarly, small veins draining the uncinate process terminate in the right and posterior aspects of the retropancreatic superior mesenteric vein. The anterior aspects of the major veins are usually free from tributaries. From the left side, the coronary vein joins the retropancreatic portal vein, and the pyloric vein joins the suprapancreatic portal vein. The superior and posterior pancreaticoduodenal veins drain into the portal vein from the right side, deep to the first part of the duodenum and opposite the pyloric vein. The coronary, or left gastric, vein usually (in 60% of cases) drains into the left side of the retropancreatic portal vein, but it may have a high termination well above the neck of the pancreas.

The close anatomical relationship of the splenic vein with the pancreas often leads to splenic vein occlusion in inflammatory or neoplastic diseases involving the body and tail of the gland. Retrograde venous drainage toward the splenic hilum and then by way of the short gastric veins and the left gastroepiploic vein creates the syndrome of left-sided portal hypertension and gastric varices.

Lymphatic drainage

The lymphatic vessels of the pancreas conform to the general pattern of deep lymphatic drainage and accompany the arterial supply (Fig. 67.5). The duodenum and head of the pancreas have a common lymphatic drainage; lymph from the foregut and midgut structures, including the pancreas, liver, stomach, spleen, small bowel, and proximal large bowel, flows eventually into the celiac and superior mesenteric groups of paraaortic nodes and into the cisterna chyli [7]. The lymphatics of the tail of the pancreas pass to the splenic nodes at the hilum of the spleen, and those of the body of the pancreas pass upward to the pancreaticosplenic nodes lying along the superior border of the gland. These nodes, along with the retropancreatic nodes, drain into the celiac nodes. Lymphatics of the upper anterior part of the head of the pancreas pass through the subpyloric nodes lying behind the first part of the duodenum. Obstruction of these pancreatic lymphatic drainage pathways by tumor may result in the shunting of

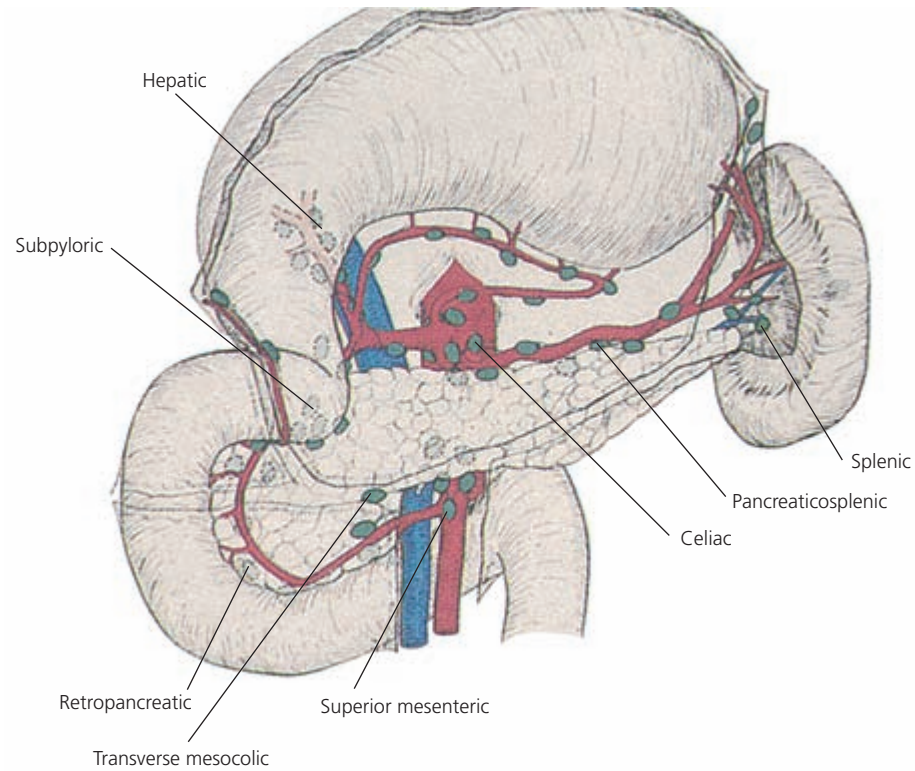

Figure 67.5 Lymphatic drainage of the pancreas. The pancreas is viewed from its anterior aspect. The gastrocolic ligament has been divided along the greater curvature of the stomach, which has been retracted anterosuperiorly. The transverse mesocolon has been detached from the peritoneum of the posterior abdominal wall. Labels indicate representative lymph nodes in the major regional nodal groups.

lymph through local collateral channels, resulting in the involvement of nodes primarily concerned with hepatic or gastric drainage. Inferiorly, the retropancreatic and antepancreatic group of nodes drain into the superior mesenteric nodes, and lymph from the latter also may pass into nodes in the root of the transverse mesocolon. The absence of fascial or retroperitoneal coverings on the posterior aspect of the pancreas allows easy communication between lymphatics of the pancreas and those of neighboring retroperitoneal tissues and organs. The lymphatic network is so rich that a thorough lymphadenectomy en bloc with a pancreatic resection frequently produces a profuse postoperative chylous leakage [8].

Nerve supply

The sympathetic efferent innervation of the pancreas is derived from the greater, lesser, and least splanchnic nerves. The bodies of the preganglionic sympathetic neurons originate in the lateral gray matter of thoracic spinal segments 5 through 10. After traversing the sympathetic trunks, presynaptic nerve fibers synapse with postganglionic sympathetic neurons within the celiac plexus, although there is some minor distribution to the pancreas through the hepatic and superior mesenteric plexuses. The celiac ganglion consists of two masses that lie on either side of the aorta, anterior to the crura of the diaphragm and close to the adrenal glands. The right celiac ganglion is partly covered by the inferior vena cava, and the left celiac ganglion is covered by the peritoneum of the lesser sac close to the upper border of the pancreas. The cell bodies of afferent sympathetic neurons are located in dorsal root ganglia. Afferent fibers often cross the midline in celiac ganglia before projecting centrally so that sympathetic afferent innervation is bilateral.

The parasympathetic innervation of the pancreas is derived from the vagal nerves. The cell bodies for efferent vagal fibers are located in the medulla in the dorsal motor nucleus. Efferent fibers pass to the pancreas by way of the celiac division of the posterior vagal trunk. No synaptic connections are made within the celiac ganglia; postsynaptic neurons are located within the pancreatic parenchyma. Afferent vagal fibers also pass through the celiac ganglia; afferent cell bodies are located within the nucleus ambiguus [9].

The ultrastructure of pancreatic innervation has been studied extensively in several animal species in addition to humans. Myelinated fibers usually are not found within the parenchyma. Intrapancreatic ganglion cells are seen within the interlobular tissues, with nonmyelinated fibers passing to both exocrine and endocrine portions of the gland. The sites of nerve termination may be generally grouped as blood vessels, pancreatic acinar cells, ductal cells, and pancreatic islets. Functional correlates suggest that pancreatic nerves may modulate the function of each of these pancreatic elements. In addition to the classic cholinergic and adrenergic neurons, evidence suggests that a large number of peptide-containing neurons also exist within the pancreas. Immunocytochemical methods have demonstrated the presence of fibers or cell bodies containing vasoactive intestinal polypeptide, substance P, cholecystokinin-8, gastrin-releasing peptide, enkephalin, galanin, neuropeptide Y, and calcitonin gene-related peptide [10,11]. The physiological actions of many of these peptidergic nerves within the pancreas remain to be defined, but anatomical studies suggest that modulation of release of acetylcholine and catecholamines from autonomic nerve terminals within the pancreas may be important. Regulation of pancreatic secretion and blood flow is also an important function of intrapancreatic neurons.

Pain fibers from the pancreas travel through the celiac ganglia and by way of the sympathetic splanchnic nerves and the thoracic sympathetic chain to reach the spinal root ganglia. Pain from the head of the pancreas tends to be broadly localized in the midepigastrium, and pain from the body and tail tends to be localized in the left upper quadrant. Visceral pain from the pancreas usually is sensed as a severe, constant discomfort in the epigastrium. Because the pancreas does not contact the somatically innervated parietal peritoneum, sharply localized pain usually does not occur. Radiation of pancreatic pain to the back in the area of the lower thoracic vertebrae is common.

Studies suggest that pancreatic innervation may be altered in disease states such as chronic pancreatitis. In patients with chronic pancreatitis, the number and diameter of intralobular and interlobular nerve bundles have been reported to be increased relative to normal. Pancreatic nerves in these patients demonstrated increased immunostaining for substance P and calcitonin gene-related peptide [12]. Because these peptides are known to be expressed in afferent neurons, the changes have been postulated to be responsible for the pain syndrome associated with chronic pancreatitis. Alterations in peptidergic pancreatic innervation also have been reported in animal models of chronic pancreatitis [13]. The hypertrophy of pancreatic nerves seen in chronic pancreatitis has been associated with increased expression of nerve growth factor (NGF) by acinar and islet cells. Expression of NGF results in increased expression of its receptor in neural tissue, and an increase in receptor expression has been shown to correlate with pain intensity [14,15]. Interactions of nerves with pancreatic inflammatory cells have been proposed as a cause [16].

Ductal system

The main pancreatic duct of Wirsung extends from the tail of the pancreas to the major duodenal papilla or ampulla of Vater (Figs 67.6 and 67.7). The average diameter of the duct in the adult tapers from 4 to 2 mm, and it is widest in the head of the gland [17]. The main duct is close and almost parallel to the distal common bile duct for 2–3 mm, then

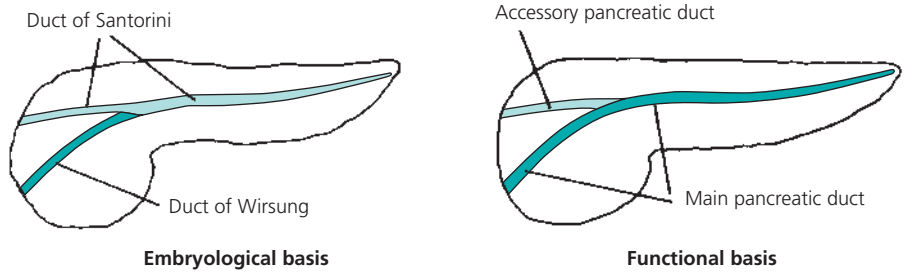

Figure 67.6 Terminology variously applied to describe the pancreatic duct system. One system indicates an understanding of ductal embryology, particularly with regard to the development of the more unusual variations **(left)**. For clarity and practicality, however, the terms given on the **right** are preferred.

combines to form a common duct channel before opening into the duodenum. The accessory pancreatic duct of Santorini, which is present in 40%–70% of people, usually communicates with the main duct and passes transversely to the right in the upper part of the head of the pancreas. The duct of Santorini lies anterior to the intrapancreatic common bile duct and usually opens into the proximal portion of the second part of the duodenum at the minor papilla, proximal to the ampulla of Vater.

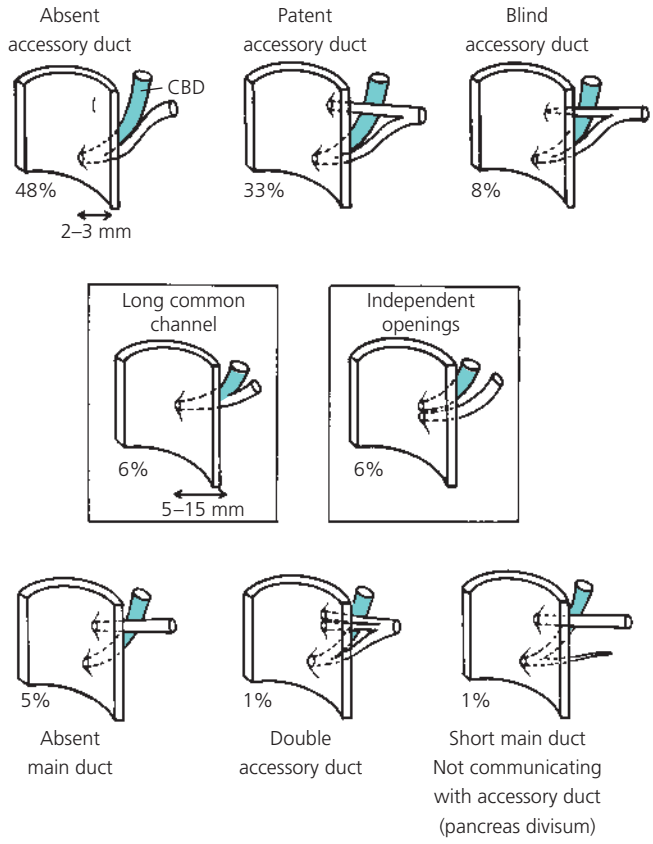

Figure 67.7 Variations of main and accessory pancreatic ducts, and their relation to the common bile duct (CBD) from a series of 143 postmortem preparations. Accessory duct variations and usual short common channel for CBD and main pancreatic duct **(top)**; variations of CBD and main pancreatic duct terminations **(middle)**; miscellaneous variations **(bottom)**. Adapted from Berman et al. [17], with permission from the Journal of the American College of Surgeons.

This "typical" ductal anatomy actually may be present in as few as 33% of people [18]. Important variations include nonpatency of the accessory duct (8%), independent openings of the common bile duct and the main pancreatic duct (6%), an absent main duct (5%), and patent double accessory ducts (1%). Noncommunication between the main duct and the accessory duct, with the body and tail of the gland draining exclusively by way of the duct of Santorini, results in the anatomical variant known as *pancreas divisum*, which occurs in 2%–6% of otherwise healthy people.

The sphincter of Oddi consists of circular smooth muscle that surrounds the common channel of the common bile duct and the main pancreatic duct at the ampulla of Vater. The muscle fibers of the sphincter of Oddi extend around the common bile duct just distal to the latter's oblique entry into the wall of the duodenum to form the choledochal sphincter. A short region of circular smooth muscle also surrounds the pancreatic duct just before its termination to form the pancreatic duct sphincter.

Ultrastructure

The pancreas is a mixed endocrine and exocrine gland. Its glandular constituents by weight are 80% exocrine tissue, 18% ductular system, and 2% endocrine tissue. Also, the pancreas is a lobulated organ with lobular subunits composed of acini; the latter are rounded or have a short tubular form and consist of single rows of epithelial cells lying on a basal lamina. Lining the lumen of the acinus are pyramidal acinar cells and pale-staining centroacinar cells, which are unique to the pancreas. The acinar lumen connects with the intralobular ducts to form the interlobular ducts, which, in turn, coalesce to form the main pancreatic duct. Lining the ductules are columnar cells, goblet cells, and occasional argentaffin cells. The large ducts are surrounded by thick layers of connective tissue and elastic fibers.

In the resting state, the basal portion of the acinar cell contains a centrally located spherical nucleus lying within a highly basophilic cytoplasm secondary to the large number of ribosomes in the rough endoplasmic reticulum. The abundant ribosomes attest to the high protein-synthesizing capacity of the acinar cells. A clear region containing the Golgi

complex separates the nucleus from numerous eosinophilic zymogen granules, each about 1 μm in diameter, lying at the apex. The acinar cell has short microvilli, averaging 0.2 μm in length, which protrude into the acinar lumen. At the apical portion, the cells are held together by tight junctions, which prevent reflux of lumenal contents. Laterally, the cells are connected by gap junctions, which permit intercellular communication.

The thin basal lamina on which the acini rest is supported by collagen fibers. A rich capillary plexus surrounds the acinus in this connective tissue, and this plexus is penetrated by numerous nerve fibers, which reach the acinar cells [19].

The endocrine portion of the pancreas consists of about one million islets of Langerhans, which are distributed throughout the gland but are relatively concentrated in the tail of the pancreas. The islets are about 200 μm in diameter, and each is associated with a prominent capillary plexus. The islets contain several cell types. About 75%–80% of islet cells are beta cells (or B cells), which secrete insulin, and 10%–20% are alpha cells (or A cells), which contain glucagon. Delta cells (or D cells) constitute about 5% of the islets and contain somatostatin [20]. The beta cells occupy the center of the islets, whereas the perimeter is lined by alpha cells. Delta cells are dispersed between these groups. Other peptide-secreting cells that may be associated with the islets include enterochromatin cells, containing 5-hydroxytryptamine, and pancreatic polypeptide cells, containing pancreatic polypeptide.

Congenital anomalies

Agenesis or hypoplasia of the pancreas

Agenesis of the pancreas is a rare and, at one time, universally fatal condition [21]. Failure of the pancreas to develop may occur as an isolated anomaly, or it may be associated with other congenital defects, such as absence of the gallbladder [22]. Although the cause is not known, pancreatic agenesis has been associated with retarded intrauterine growth, presumably resulting from failure of the endocrine pancreas to produce insulin [23]. Partial agenesis of the pancreas results from incomplete formation of either the dorsal or ventral pancreas and has a more favorable outcome than complete agenesis. Involvement of the dorsal segment appears to be more common than involvement of the ventral pancreas. These glands possess normal exocrine and endocrine function.

Hypoplasia of the pancreas is a congenital disease involving exclusively the exocrine pancreas and has been referred to as lipomatous pseudohypertrophy of the pancreas [24]. Pathologically, the gland appears enlarged and of normal shape but of a fatty consistency. The major pancreatic ducts are developed, and islets of Langerhans are present; however, secondary pancreatic ducts and acinar lobules are absent or underdeveloped, and fatty tissue replaces normal acinar cells [25]. The finding that the gland is of normal shape, but missing differentiated cellular components, led investigators to postulate that embryological development is normal in this condition. It is proposed that an intrauterine insult occurs, such as infection, causing hypoplasia of the exocrine gland [26]. Although this disease usually is diagnosed in infants, it has been reported to occur in adults sometimes in association with malignancy [24,25,27]. It is also seen in two autosomally recessive diseases, Shwachman–Diamond syndrome and Bannayan–Riley–Ruvalcaba syndrome [28,29]. Manifestations result from severe pancreatic exocrine insufficiency.

Annular pancreas

Annular pancreas is an unusual complication of disturbed embryological development in which the head of the pancreas surrounds the duodenum, often resulting in duodenal obstruction. Annular pancreas frequently is associated with other congenital defects, including Down syndrome, Meckel diverticulum, malrotation of the intestine, duodenal atresia and bands, intestinal webs, tracheoesophageal fistulas, imperforate anus, absence of the gallbladder, and certain types of cardiac defects [30–34]. Annular pancreas has been described in association with pancreas divisum (see "Pancreas divisum" below) [35]. Men appear to be affected more commonly than women. The occurrence of annular pancreas is usually sporadic, although several reports describe a familial association and apparent autosomal dominant transmission [36–39].

Typically, the annulus is a band of pancreatic tissue completely encircling the second portion of the duodenum (Fig. 67.8). The ring usually lies proximal to the major papilla, and

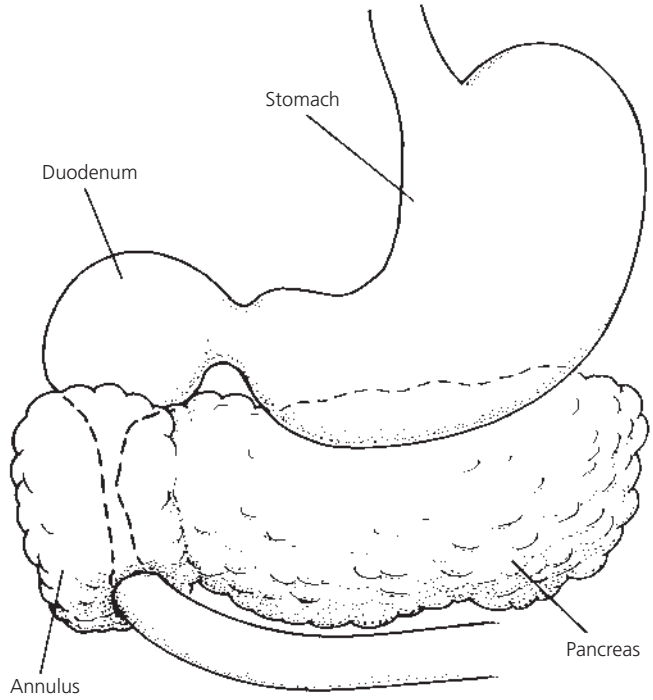

Figure 67.8 Annular pancreas. A band of pancreatic tissue surrounds the midportion of the duodenum.

in a few cases the annulus involves the first or third portion of the duodenum. Histologically, pancreatic tissue frequently invades the muscularis layer of the duodenum [40].

The most popular etiological theory suggests that the ventral pancreatic bud becomes fixed; as the pancreas and duodenum rotate, a band of pancreatic tissue is left encircling the duodenum [41]. Supporting this theory is the report that a high concentration of pancreatic polypeptide cells, which is characteristic of the ventral pancreas, was found in annular tissue [42]. Other theories propose that hypertrophy of the dorsal and ventral ducts or ectopic pancreatic tissue causes the annulus [43].

More than half of all cases are diagnosed in the first year of life. Severe duodenal stenosis is usually apparent within the first few days of birth. Because pancreatic tissue encircles the duodenum, causing obstruction, newborns and infants are intolerant of oral feedings and have vomiting, often of bilious material. Upper abdominal distention and visible peristalsis are often present on physical examination [44]. Although vomiting is the usual presenting symptom in children, adults often complain of postprandial colicky abdominal pain, bloating, and fullness that also may be associated with nausea and vomiting [45–48]. Upper gastrointestinal bleeding and duodenal ulcer disease occur in one-third of adults, and acute pancreatitis is a common associated finding in this disorder.

The radiographic signs of annular pancreas are those of duodenal obstruction. Plain radiographs of the abdomen often show a "double-bubble" sign resulting from dilation of the duodenum and stomach. With high degrees of obstruction, a duodenal cutoff sign also may be seen. In infants, these findings are the only necessary radiographic tests. Radiographic findings are not specific in older children and adults, and it is usually necessary to document duodenal obstruction by upper gastrointestinal contrast studies. Constricting bands, 0.8–5 cm long, around the duodenum have been detected radiographically [49]. Other signs include dilation and reverse peristalsis of the proximal duodenum. Endoscopic evaluation of annular pancreas usually is not helpful, although endoscopic ultrasound will occasionally reveal a circumferential band-like structure with the same echo pattern as the pancreas surrounding the duodenum [50]. The mucosa usually is normal, and it is difficult to appreciate mild narrowing of the duodenum. In severe cases, concentric narrowing of the duodenum or stenosis and associated peptic ulcer disease are suggestive of the diagnosis. Endoscopic retrograde cholangiopancreatography (ERCP) has been used to visualize the ductal system in annular pancreas and is diagnostic of the disorder [51–54]. Magnetic resonance (MR) pancreatography is being used with increasing frequency as a noninvasive alternative to diagnostic ERCP in the evaluation of pathological conditions of the pancreas such as annular pancreas and pancreas divisum [55]. Characteristic features can also be determined by CT [56]. In symptomatic patients, treatment of annular pancreas is surgical alleviation of the obstruction. Division of the annulus is not recommended because of the high incidence of pancreatitis and pancreatic fistulae complicating that procedure, and bypass of the obstructed intestinal segment is preferred [57].

Heterotopic pancreas

Aberrant localization of pancreatic tissue, also known as heterotopic pancreas or pancreatic rests, refers to segments of pancreatic tissue not in continuity with the main body of the pancreas. The condition is usually asymptomatic, and therefore its true incidence is difficult to determine. Heterotopic pancreas has been identified in 1 of every 500 laparotomies, and autopsy studies have reported frequencies ranging from 0.6% to 15% [58,59]. Seventy percent of such rests are found along the upper gastrointestinal tract, with the stomach (25.5%), duodenum (27.7%), and jejunum (15.9%) representing the most frequent locations. Other intraabdominal locations include the gallbladder, liver, small intestine, colon, appendix, omentum, and Meckel diverticulum [60–62]. In the stomach, pancreatic rests are found primarily in the prepyloric region along the greater curvature. Extraabdominal sites include the lung and umbilicus [63–65]. Histologically, heterotopic pancreas can contain acinar tissue, islets, ducts, or any combination thereof. Seventy-five percent of rests are located in the submucosa of the stomach or intestine and appear as firm, yellow nodules, 2–4 cm in diameter, underlying the mucosa. These often have a central mucosal depression, thought to represent the presence of a vestigial duct, that may be recognized endoscopically or by radiographic contrast studies. The origin of heterotopic pancreas is not known, and it is likely that several abnormalities of embryological development account for the locations in various sites. As pluripotential cells, pancreatic rests may represent abnormal differentiation of endodermal stem cells. Conversely, disturbances in migration of the pancreas as it rotates around the gut may account for some heterotopic locations [66].

Heterotopic pancreas is usually an asymptomatic condition that is an incidental finding at surgery or autopsy. Symptoms attributed to this disorder include abdominal pain, nausea, vomiting, and gastric outlet obstruction [67,68]. Peptic ulcer disease and upper gastrointestinal bleeding also have been described. Because of the varied locations of pancreatic rests, involvement of other organs can occur. Pancreatitis, biliary obstruction with jaundice, intestinal obstruction, and intussusception all have been associated with heterotopic pancreas [69–75]. As a result of the combined exocrine and endocrine function of the pancreas, any pathological change in the normal pancreas also can occur in ectopic tissue [76]. Therefore, malignant degeneration, cyst formation, and islet cell tumors also may be found in pancreatic rests [77–83].

Pancreatic rests involving the upper gastrointestinal tract often are detected initially by contrast radiography or endoscopy as a submucosal bulge with central umbilication [84,85]. These lesions are covered by normal mucosa, making routine

endoscopic biopsy impossible. Heterotopic pancreas may be difficult to differentiate from leiomyomas, fibromas, carcinoid tumors, or other malignant tumors. Endoscopic ultrasound (EUS) has become an increasingly useful modality in the evaluation of these submucosal gastrointestinal masses. It not only can distinguish between an intramural lesion and compression from an extralumenal mass, but also allows identification of the wall layer from which the mass originates. For example, pancreatic rests, located in the submucosal layer, can be differentiated from leiomyomas, the most commonly encountered submucosal masses, which are located in the layer of the muscularis propria [86]. In other cases in which a definitive diagnosis cannot be made based on EUS appearance, EUS-guided fine-needle aspiration may be used to obtain a histological diagnosis [87,88].

Treatment of ectopic pancreatic tissue is indicated only for those who have significant symptoms or complications, such as recurrent upper gastrointestinal bleeding, biliary or intestinal obstruction, or malignant degeneration. Definitive treatment is surgical removal of the ectopic tissue. Asymptomatic people with incidental discovery of heterotopic pancreas do not require further evaluation or treatment [89]. If unsuspected pancreatic rests are found at surgery, excision prevents the possible complication of malignant degeneration and eliminates confusion if subsequent symptoms develop [89,99].

Pancreas divisum

Pancreas divisum, the most common congenital anomaly of the pancreas, is caused by failure of the ducts of the dorsal and ventral anlagen to fuse during the fifth and sixth weeks of gestation. Normally, the proximal one-third of the dorsal pancreatic duct regresses as it fuses with the ventral duct, forming the main pancreatic duct. In pancreas divisum, the ventral duct of Wirsung empties into the duodenum through the major papilla but drains only a small portion of the pancreas. Secretions from the tail, body, neck, and remainder of the head of the pancreas drain into the duodenum through the minor papilla by way of a persistent duct of Santorini. In 2%–3% of cases in which the ducts do not fuse, the ventral duct may not be demonstrable. Normally, drainage of the pancreas can occur by either duct, depending on fusion of the two ductal systems and the degree of patency of each. Most pancreatic drainage is through the duct of Wirsung, and although some drainage occurs through the duct of Santorini, this volume is relatively small. Occasionally, the duct of Santorini ends blindly in the duodenal wall.

Although pancreas divisum is a long-recognized entity, only with the advent of ERCP has its clinical significance become apparent. In autopsy series, pancreas divisum has an incidence of 5%–10% [90]; as an ERCP finding, its incidence is 4% [91–93]. In a series of patients with pancreatitis, however, there was a 16% incidence of pancreas divisum, and the incidence of the abnormality increased to 25% in idiopathic pancreatitis [91]. Therefore, it appears that pancreas divisum is associated with pancreatitis. It has been postulated that pancreatitis may result from a combination of pancreas divisum and stenosis at the level of the accessory papilla, with impediment of pancreatic secretory flow. As a congenital defect, clinical manifestations of pancreas divisum may occur at any age but are uncommon in childhood. Symptoms may be mild with only occasional epigastric pain occurring postprandially, but more often episodes of severe acute pancreatitis occur. Chronic pancreatitis also may develop, with all of its associated sequelae. Changes in the pancreatic ducts characteristic of chronic pancreatitis may be detected on ERCP.

Pancreas divisum is diagnosed by pancreatography (Fig. 67.9). On ERCP, the major papilla is often difficult to cannulate, but on injection with contrast fluid, the duct of Wirsung appears shortened and of small diameter. There is rapid filling of small accessory ducts, and too much contrast can be injected before it is realized that the duct of Wirsung is not in communication with the main pancreatic duct. As a result, the patient may experience sudden pain, and pancreatitis of the ventral pancreas can develop. What appears as an abrupt cutoff of the duct of Wirsung must not be confused with a mass lesion such as a malignancy or pancreatic pseudocyst. The delicate nature of the accessory ducts on the pancreatogram is a helpful indicator of pancreas divisum. If possible, the accessory papilla should be cannulated, which should reveal a duct of Santorini running the entire length of the pancreas that is not in communication with the duct of Wirsung. Although ERCP remains the gold standard for diagnosis of pancreas divisum, MR pancreatography is an emerging, noninvasive radiographic technique that is being used to define ductal anatomy (see "Annular pancreas" above). If stenosis of the papilla is not demonstrated radiographically, pancreatic manometry and secretin ultrasound scanning may be useful in identifying patients who may benefit from endoscopic or surgical intervention [94,95].

Figure 67.9 Pancreas divisum. An endoscopic retrograde pancreatogram performed through the accessory papilla shows the dorsal duct in pancreas divisum. Courtesy of Peter B. Cotton, Durham, NC.

Patients with mild symptoms can be managed conservatively. Patients with recurrent episodes of acute pancreatitis or chronic pain require intervention to alleviate accessory ductal stenosis. Surgical accessory duct sphincteroplasty has been successful in treating patients, with the best results observed in patients with recurrent episodes of acute pancreatitis [96–98]. Endoscopic therapy with a combination of minor duct sphincterotomy and stenting has achieved similar rates of success; however, the follow-up period in these patients has been less than in the surgical groups [99–101], and long-term stenting of the pancreatic duct has been reported to result in chronic ductal changes [102]. Determination of which patients with acute recurrent pancreatitis would be served best by surgical or endoscopic treatment awaits further studies. Patients with chronic pancreatitis have a poor response to both surgical and endoscopic treatment modalities. In cases in which sphincterotomy has failed or the ductal involvement is more extensive, direct ductal drainage or resection of the involved pancreas is necessary [103,104].

Congenital cysts

Cysts of the pancreas are distinguished from more common pseudocysts by the presence of an epithelial lining. Pseudocysts often follow bouts of acute pancreatitis, with trauma being a major precipitant. Identification of true columnar or cuboidal epithelium in congenital cysts may be difficult, and it is not always possible to distinguish a congenital cyst from a pancreatic pseudocyst. In cysts located in the peripancreatic space, identification of pancreatic enzymes in the cyst fluid is helpful in determining that it is of pancreatic origin; however, not all pancreatic cysts contain fluid rich in pancreatic enzymes. Solitary congenital cysts are rare [105]. They are more commonly diagnosed in early childhood but may remain asymptomatic and undetected into adulthood. Although other congenital anomalies have been reported with pancreatic cysts, these are more often isolated defects [106].

The most common presentation of a solitary pancreatic cyst is as an abdominal mass, which may be associated with abdominal pain or complications resulting from expanding size, such as gastroduodenal obstruction. Encroachment on the intrapancreatic or extrapancreatic common bile duct may cause biliary obstruction [107]. Subcutaneous fat necrosis and osteolytic lesions secondary to pancreatic enzymes leaking into the circulation from a developmental pancreatic cyst have been described [108].

The presence of a pancreatic cyst may be suggested by a plain radiograph of the abdomen or an upper gastrointestinal radiographic series demonstrating a mass displacing a portion of the stomach, duodenum, or colon. The best diagnostic test is CT, which demonstrates a fluid-filled cystic lesion in the pancreas and its relationship to surrounding structures. In considering the differential diagnosis, it is important to consider other possible cystic lesions of the pancreas, including pancreatic pseudocysts, cystadenomas, and cystadenocarcinoma.

Cystic neoplasms of the pancreas are rare, representing about 10% of pancreatic cysts and 1% of pancreatic carcinomas [109]. Abdominal or back pain, the most common symptom, is present in about half of patients. One-third of patients have an abdominal mass or weight loss, and one-third of patients are asymptomatic, with the cyst discovered during evaluation of other complaints. There is a clear predilection for women, with a female-to-male ratio of 8:1. Computed tomography is the most useful diagnostic modality and typically reveals a multiloculated lesion measuring 3–6 cm, located in any region of the pancreas. Two major histological variants exist: serous cystadenomas and mucinous cystic neoplasms. Mucinous cystic neoplasms of the pancreas have clear malignant potential. Serous cystadenomas, by contrast, are almost invariably benign. Preliminary experience with biochemical and cytological analysis of cyst fluid to distinguish serous and mucinous neoplasms has been disappointing. Carcinoembryonic antigen (CEA) has been the most useful marker of malignancy in cyst fluid obtained by endoscopic ultrasound-guided fine needle aspiration, but it still has an accuracy of only 79%. The accuracy of cytology has been shown to be poor (59%), and no combination of tests, including EUS appearance, has been shown to be more accurate than CEA alone. Work is underway to determine the utility of proteomic and DNA analysis of cyst fluid in the differentiation of benign from malignant cystic neoplasms [110–112]. The differentiation of congenital cysts, acquired pseudocysts, and cystic neoplasms is crucial. The operative therapy for chronic pseudocysts is nonresectional, whereas therapy for cystic neoplasms requires resection [113].

Symptomatic congenital cysts should be removed whenever possible, which can be done by enucleation of the cyst if it is located in the body or head of the pancreas, or by resection of the cyst with adjacent pancreatic tissue if it is confined to the distal pancreas. If either of these approaches is precluded by the location of the cyst, such as a cyst in the head of the pancreas, drainage into the stomach or jejunum can be performed. With surgical drainage of the cyst, pathological examination should be done to exclude malignancy.

Multiple cysts

Multiple congenital pancreatic cysts are rare and usually associated with other congenital anomalies, most frequently polycystic kidney disease and cystic fibrosis. Other clinical syndromes involving multiple pancreatic cysts include von Hippel–Lindau syndrome, Ivemark syndrome, and Bruber syndrome, in which cysts of the lung, liver, and central nervous system also are found [114,115]. Many of the associated anomalies are lethal, although patients may have no symptoms referable to the pancreatic cysts. Because of the numerous cysts and the involvement of several organ systems, no treatment is necessary unless specific symptoms or a

particular complication, such as infection of a cyst, dictates surgical excision or drainage.

The reader is directed to Chapter 15 (Pancreatic secretion) and Chapter 72 (Hereditary diseases of the pancreas).

Definition

Acute pancreatitis is a disorder primarily of the exocrine pancreas that involves varying degrees of acute inflammation associated with parenchymal injury of the gland. In its most severe forms the parenchymal injury is manifest as necrosis of pancreatic tissue and dysfunction of other organs both adjacent to and distant from the pancreas. The clinical syndrome resulting from an episode of acute pancreatitis includes the rapid onset of abdominal pain with variable abdominal findings ranging from mild tenderness to peritoneal signs. The disease is often accompanied by vomiting, fever, tachycardia, leukocytosis, and increased levels of pancreatic digestive enzymes in the blood and urine. In severe cases there is dysfunction of other organ systems (i.e., pulmonary, renal, cardiovascular, hepatic, central nervous system, and adipose tissue).

Epidemiological studies demonstrate that approximately 70% of cases of acute pancreatitis are related to biliary stones or alcohol abuse [1]. Numerous other etiologies account for another 20%, and about 10% of cases are idiopathic despite extensive evaluation. Although there are many potential etiologies for acute pancreatitis, only a few of the etiologies (i.e., alcohol abuse, genetic disorders, and hyperlipidemia) lead to chronic pancreatitis. The mechanisms underlying the transition from acute pancreatitis to chronic pancreatitis are unknown.

The first systematic description of acute pancreatitis was published by Reginald Fitz in 1889 [2]. The paper described the clinical and pathological findings in 53 patients with this disorder. The descriptions included the pattern of abdominal pain as well as clinical observations such as fever, jaundice, and abdominal findings. Fitz's paper established the initial diagnostic criteria for pancreatitis. The report presented evidence for etiological factors such as gallstones, alcohol abuse, trauma, and penetrating peptic ulcers; and pathological findings of pancreatic pseudocysts, pancreatic abscess, splenic vein thrombosis, and disseminated fat necrosis. Thus, the description of acute pancreatitis by Fitz set the stage for mechanistic and clinical studies designed to improve prevention, diagnosis, and treatment of this disorder.

Incidence

The incidence of acute pancreatitis ranges from 5 to 73 per 100 000 per year [3–8]. This incidence is an approximation for several reasons. First, the incidence is subject to variations between populations and ethnic groups as a function of the prevalence of precipitating factors such as alcohol abuse and biliary stone disease. Second, histological confirmation is available for only a few patients with acute pancreatitis. The diagnosis is often presumptive and based on clinical assessment with accompanying laboratory and imaging tests, all having limited sensitivity and specificity. Finally, some patient groups may not come to medical attention because of mild disease or because of limited access to medical care.

Reports from some countries [1,3–6,8] show a slightly greater incidence of acute pancreatitis in males compared with females. Further, in reports where precipitating factors are considered, alcohol abuse is more commonly associated with male cases than female cases, whereas gallstone disease is more commonly associated with female cases than male cases [3,5,6]. Thus, the total incidence and the gender distribution of cases of acute pancreatitis in different areas of the world are greatly influenced by the incidence of alcohol abuse and gallstone disease.

Classification

The simplest way to classify acute pancreatitis is by histology. Mild interstitial pancreatitis and severe necrotizing pancreatitis (Fig. 68.1) represent the two extremes of the disease. However, histological examination of the tissue is rarely possible. Considering this situation, other classification systems of acute pancreatitis have been devised that consider the potential causative factor(s) or severity of illness. These systems use sets of information from clinical observations, laboratory tests, and imaging studies. Several of these systems are discussed in more detail later in the chapter.

A sensible and useful approach, proposed by an international symposium convened in Atlanta [9], separates acute pancreatitis into mild and severe disease based on a combination of clinical findings, laboratory tests, and imaging studies. Mild pancreatitis is not associated with local or systemic complications and recovery is usually uneventful without need for medical or surgical interventions other than accepted supportive care. However, severe pancreatitis is associated with impaired pancreatic function, local or systemic complications, the need for medical or surgical interventions, and a significant mortality rate. In cases of severe pancreatitis, the Atlanta classification provides definitions for both systemic and local complications.

Careful determination of the local and systemic complications in cases of severe pancreatitis promotes optimal care of such patients. Cases of severe acute pancreatitis require the collaboration of gastroenterologists, intensivists, radiologists, and surgeons accurately to diagnose complications and to apply appropriate treatments.

(c)

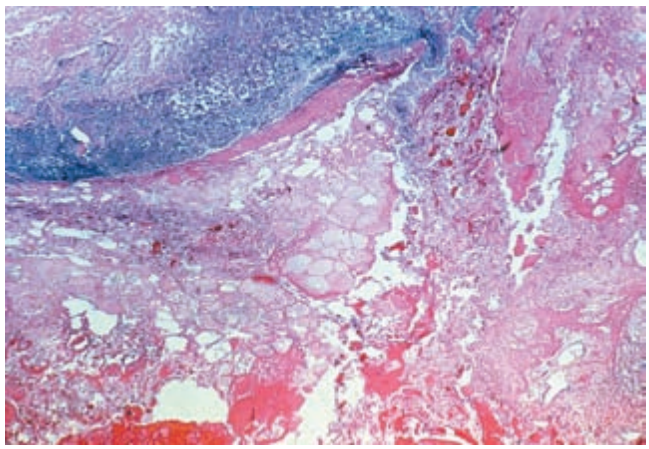

Figure 68.1 **(a)** Histology of the normal exocrine pancreas. This histological (H & E stain) image of pancreatic tissue features mostly pancreatic acini. Of note, pancreatic acinar cells are arranged in a spherical or tubular structure, the acinus, with basally located nuclei and apical lumen. The red (eosinophilic) staining in the apical area results from acidic zymogen granules. The blue staining in the basal area results from basic endoplasmic reticulum and the nucleus. The dark nuclei are located at the base of the acinar cells. There is a small pancreatic ductule in the upper right center part of the image adjacent to an acinus. There are no islets of Langerhans in the photomicrograph. **(b)** Histology of mild acute pancreatitis. Mild (edematous) pancreatitis is associated with edema, mild to moderate pancreatic inflammation, and acinar cell vacuolization with preservation of pancreatic architecture. At stages later than shown in this micrograph there is mild necrosis, especially of fat (not shown). **(c)** Histology of severe acute pancreatitis. Severe disease is associated with loss of pancreatic architecture, severe inflammation, edema, necrosis of fat and parenchymal tissues, vascular injury, and hemorrhage. Courtesy of K. Barwick, Jacksonville, FL. From Gorelick et al. [312], with permission. Copyright, American Gastroenterological Association Institute, Bethesda, MD.

Pathobiology

Overview

As indicated above, the clinical associations accounting for 70%–80% of the cases of acute pancreatitis are alcohol abuse and gallstone disease. How these two associations are involved in the causation or initiation of pancreatitis is not established. However, significant progress has been made in identifying

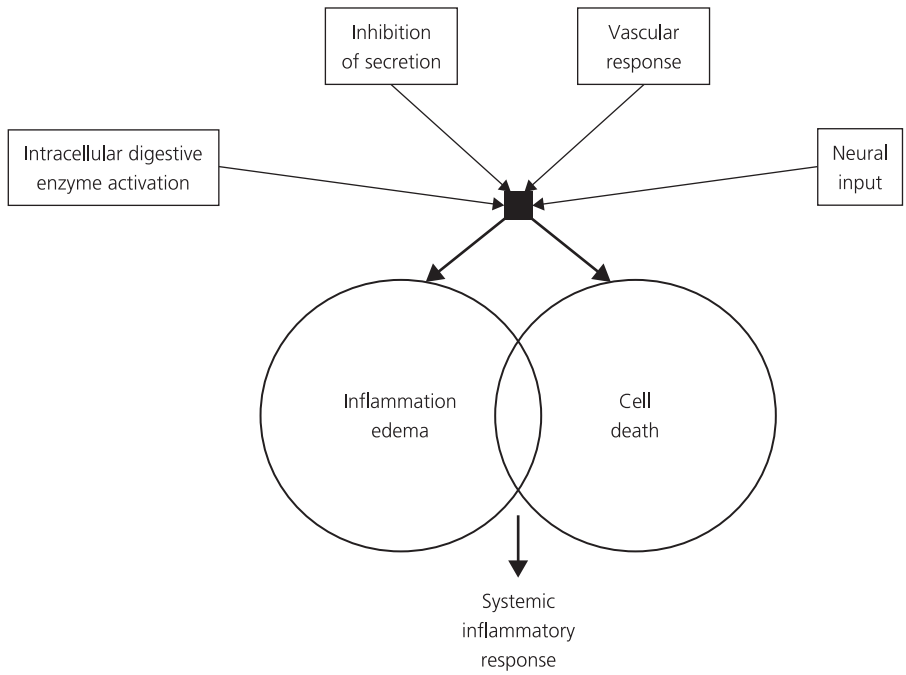

Figure 68.2 Schematic showing the major pathobiological processes of acute pancreatitis, namely inflammation/edema and cell death. The interactions between these processes are discussed in the text. Regulators of these processes include intracellular digestive enzyme activation, inhibition of secretion, and vascular and neural inputs. In severe acute pancreatitis the pancreatic pathobiological responses lead to the systemic inflammatory response.

key steps that mediate the major pathobiological processes (i.e., inflammation/edema and cell death) using experimental animal models of pancreatitis. Such investigations are leading to the identification of molecular targets for therapy.

The major pathobiological processes of acute pancreatitis are influenced by the participation of unique pancreatic intracellular and extracellular events or factors. Examples of intracellular events are activation of digestive enzymes and inhibition of secretion that occur during pancreatitis. Examples of extracellular factors include vascular and neural participation in pancreatitis. The following sections describe the experimental models of pancreatitis and the mechanisms of the major pathobiological processes occurring during pancreatitis, including participation of intra- and extracellular events and factors. Figure 68.2 provides a conceptual framework for considering the relationships between the major pathobiological processes; modulation of these processes by unique pancreatic factors; and the effects on other organ systems through the systemic inflammatory response that occurs with severe pancreatitis.

Experimental models

There are two principal functions for animal model research in acute pancreatitis. First, the models provide the ability to reveal the sequence of molecular steps resulting in the pathobiological processes of acute pancreatitis. Human pancreatic tissue is rarely available for such investigations. Animal models can be used both to identify early signals leading to disease, and to demonstrate roles for each signal in the mechanism of each of the pathobiologic processes using pharmacologic and genetic strategies to specifically alter the activity of these signals.

The second principal use for animal models is to evaluate potential therapies. There are considerable difficulties in designing human clinical trials because the disease varies so widely in its course and severity. In addition, there is a low incidence of the most severe forms of pancreatitis, where testing agents for therapeutic benefit would have the most value. Because of the low incidence of severe forms of acute pancreatitis, multicenter collaborative studies are usually required for definitive evaluation of novel therapies. Animal models of acute pancreatitis can assist by providing information to help select the most promising therapeutic agents for testing.

There are several animal models of acute pancreatitis [9–18]. The more commonly used models are listed in Table 68.1. Which animal model to use for a particular experiment depends first on the purpose of the experiment. For example, for studies testing a potential therapy, models with more severe pancreatitis and systemic inflammation should be used because the severity of pancreatitis in both animals and humans is directly related to the amount of necrosis [11,12,18–21]. For studies designed to reveal early signals underlying a pathobiological response, such as inflammation or cell death, the most important features are uniform severity and time course of the disease in the animal model chosen. It is of note that with the wider availability of genetically modified mice, experimental models of acute pancreatitis are often used to test the participation of specific biochemical pathways [15].

Table 68.1 Models of experimental acute pancreatitis

Models	Species	Features
Cholecystokinin analogues (parenteral)	Rat	Pancreatic inflammation, apoptosis, mild necrosis. Systemic inflammation
Cholecystokinin analogues (parenteral)	Mouse	Pancreatic inflammation, severe necrosis. Systemic inflammation
Pancreatic duct obstruction	Rat	Pancreatic apoptosis
Pancreatic duct obstruction	Opossum	Pancreatic inflammation, severe necrosis. Systemic inflammation
Bile acid perfusion of pancreatic duct	Rat	Pancreatic inflammation, severe necrosis. Systemic inflammation
Choline-deficient, ethionine-supplemented diet	Mouse	Pancreatic inflammation, severe necrosis. Systemic inflammation
Arginine (parenteral)	Rat	Pancreatic inflammation, severe necrosis. Systemic inflammation
Alcohol diet and cholecystokinin analogues (parenteral)	Rat	Pancreatic inflammation, mild necrosis. Systemic inflammation

Alcohol metabolism in the pancreas

The liver is the major ethanol-metabolizing organ in the body. There ethanol is metabolized mainly by an oxidative system converting ethanol first to acetaldehyde and then to acetate using the enzymes alcohol dehydrogenase and acetaldehyde dehydrogenase, respectively [22]. An alternative pathway for ethanol metabolism is through the transient formation of fatty acid ethanol esters (FAEEs). Several organs including the pancreas use this pathway in ethanol metabolism [23–25]. The esterification of ethanol with fatty acids probably requires more than one enzyme system in the pancreas [26]. Compared with the liver, the activity of FAEE synthesis is greater in the pancreas [23,26–29]. By contrast, oxidative metabolism of ethanol in the pancreas is much less than that in the liver.

The formation of FAEEs may have significant pathological effects in the pancreas [27,30–32]. These include activation of proinflammatory transcription factors that participate in the inflammatory response; increased lysosomal fragility, which enhances cell death pathways through intracellular activation of digestive enzymes; and increased cytosolic and mitochondrial calcium levels, which also activate cell death pathways. Thus, the formation of FAEEs in the pancreas during alcohol abuse represents one way in which alcohol sensitizes the pancreas to the development of acute pancreatitis.

Inflammation/edema

An early event in the mechanism of acute pancreatitis is the activation of inflammation-mediating signals originating in the pancreatic parenchymal cells (i.e., the pancreatic acinar cell). For example, the acinar cell is capable of responding to noxious stimuli by activation of signals such as nuclear factor-κB (NF-κB) and activation protein-1 (AP-1) as well as p38 mitogen-activated protein (MAP) kinase to increase the expression of various cytokines and chemokines and other inflammatory molecules [18,33,34] (Fig. 68.3). The

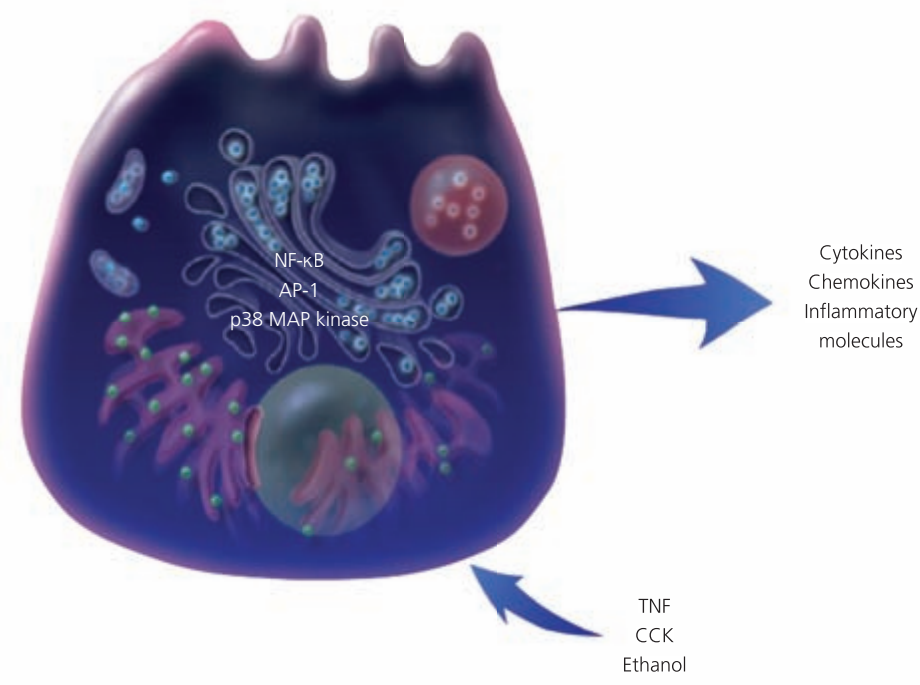

Figure 68.3 Pancreatic intracellular inflammatory response. Insults to the pancreatic acinar cell lead to upregulation of intracellular signaling systems such as nuclear factor-κB (NF-κB), activating protein-1 (AP-1), and p38 mitogen-activated protein (MAP) kinase. The signaling systems upregulate the production from the pancreatic acinar cell of cytokines, chemokines, and growth factors, which mediate the inflammatory response of acute pancreatitis. The activation of the intracellular signals can occur with supraphysiological doses of certain forms of cholecystokinin (CCK) hormone and with tumor necrosis factor-α (TNF-α). Ethanol treatment and bile acids also stimulate this inflammatory signaling or sensitize the cell to CCK and TNF-α. Adapted from Gorelick et al. [312], with permission. Copyright, American Gastroenterological Association Institute, Bethesda, MD.

proinflammatory cytokines/chemokines include tumor necrosis factor-α (TNF-α), platelet-activating factor (PAF), interleukin-6 (IL-6), IL-8, IL-1β, monocyte chemotactic protein-1, and macrophage migration inhibitory factor, among others. Other inflammatory molecules upregulated by these signaling systems include nitric oxide synthase (NOS) and intercellular adhesion molecule-1 (ICAM-1). Furthermore, ethanol feeding sensitizes the pancreas to this inflammatory response, representing another way in which alcohol abuse results in acute pancreatitis [35].

The importance of the production of the various cytokines/chemokines and inflammatory molecules in the progression of pancreatitis comes from studies in experimental models using strategies to prevent the upregulation of a specific molecule and hence determine the effect on outcome (i.e., severity of pancreatitis; Fig. 68.4). A good example comes from an experiment in animals with a genetic deficiency in ICAM-1 [33]. This molecule, which is expressed on the vascular endothelial cells and becomes activated during inflammation, is necessary for migration of neutrophils into the parenchyma during an inflammatory process. In animals with genetic deletion of ICAM-1, pancreatitis severity is markedly decreased. In a like manner, removal of neutrophils before the induction of pancreatitis results in marked reduction in the severity of pancreatitis [36]. Further, other experimental pancreatitis studies demonstrate that the recruitment of inflammatory cells into the pancreas results in both intracellular activation of digestive enzymes and necrosis [36,37]. Finally, cytokines such as TNF-α can have a direct effect on the pancreatic cells to induce cell injury and death [38].

In addition to causing pancreatic parenchymal cell injury and necrosis, the pancreatic inflammatory response is also central to the systemic inflammatory response, such as the adult respiratory distress syndrome (ARDS) that occurs in severe acute pancreatitis (Fig. 68.5) [39–44]. Chemokines/cytokines from the pancreas lead to ARDS by acting directly on lung tissue and through activation of neutrophils in the general circulation that lodge in the lung.

Treatments designed specifically to inhibit a cytokine/chemokine are unlikely to be of benefit because of the redundant nature of the system. This consideration has led to investigations in experimental models using agents known to inhibit the key signaling systems, such as those involved in production of the inflammatory response, showing potential benefit of this approach [34,45,46].

Although pancreatic edema is clearly part of the inflammatory response, the best evidence for the coordination of inflammation and edema comes from reports investigating the role of the neural system in both inflammation and edema. This evidence is discussed below (see "Neural input").

Cell death (necrosis and apoptosis)

Mechanisms of cell death in acute pancreatitis have emerged as a critical topic for investigation (Fig. 68.6). This is important because pancreatic cell necrosis is associated with severe pancreatitis and poor outcome [11,12,18–21]. Strategies aimed at inhibiting or preventing necrosis during pancreatitis may improve outcome in patients with severe pancreatitis.

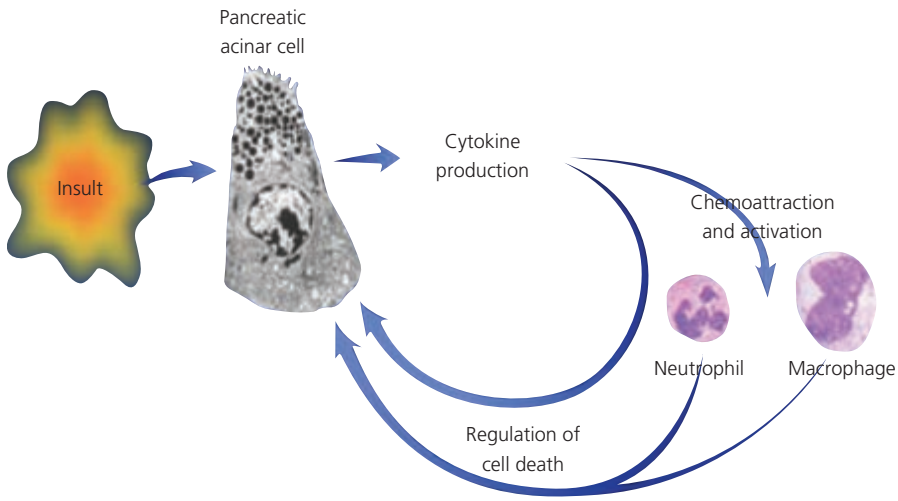

Figure 68.4 A model for the relationship between the inflammatory response and cell death response in acute pancreatitis. An insult to the pancreatic parenchymal cell, the acinar cell, leads to production of cytokines and chemokines that, in turn, have direct effects in the pancreatic parenchymal cells thereby causing a death response. Furthermore, the cytokines/chemokines recruit an inflammatory response that, in turn, mediates cell injury and death responses in the pancreatic parenchymal cells. Tumor necrosis factor-α (TNF-α) is an example of a cytokine that is produced by pancreatic acinar cells and can mediate a cell death response in the pancreatic acinar cell in an autocrine fashion. Examples of cytokines/chemokines produced by the pancreatic acinar cell that can mediate the inflammatory response include TNF-α, interleukin-6 (IL-6), IL-8, and monocyte chemotactic peptide-1 (MCP-1). Adapted from Gorelick et al. [312], with permission. Copyright, American Gastroenterological Association Institute, Bethesda, MD.

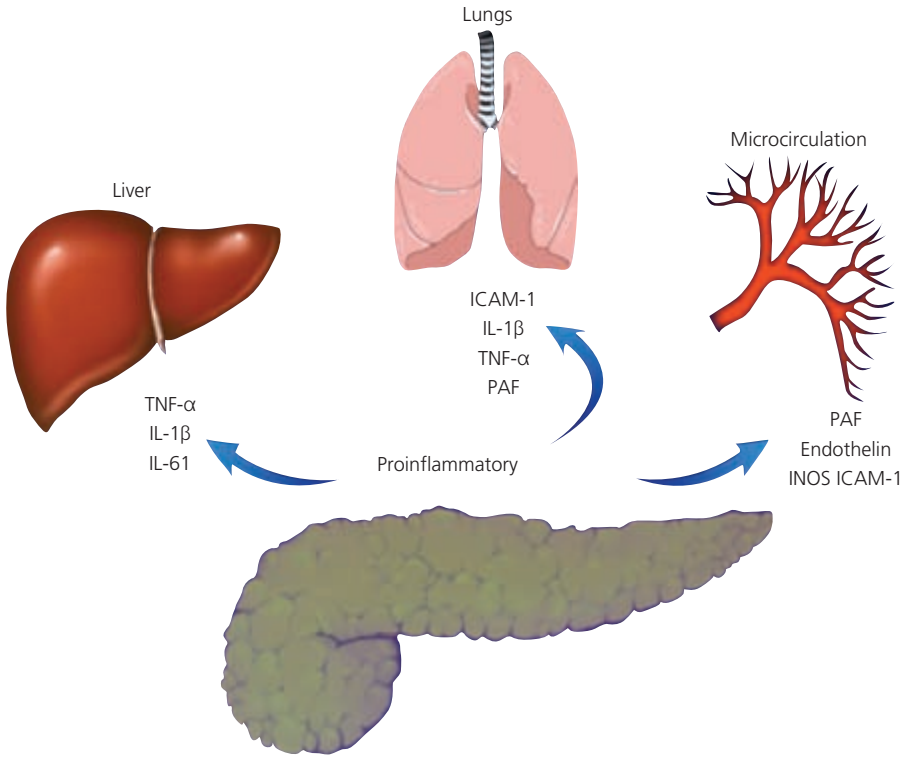

Figure 68.5 Severe pancreatitis results in liver, lung, and vascular dysfunction mediated by cytokines that are produced in the pancreas. These pancreas-derived cytokines act both directly on target tissue causing cellular injury and organ dysfunction, and indirectly by activating neutrophils in the circulation that lodge in the organ and mediate the deleterious response in the distant organ. ICAM-1, intercellular adhesion molecule-1; IL-1β, interleukin-1β; IL-61, interleukin-61; INOS, inducible nitric oxide synthase; PAF, platelet-activating factor; TNF-α, tumor necrosis factor-α. There are two major categories of cell death in experimental acute pancreatitis models – apoptosis and necrosis. Apoptosis, also called programmed cell death, is required for normal development and tissue homeostasis, but can also occur in pathological conditions [47–50]. An apoptotic cell undergoes a cascade of molecular events ultimately leading to its total removal. These events result in morphological changes that include shrinkage of the cell and its organelles and condensation of nuclear chromatin. The molecular signals of apoptosis also lead to translocation of phosphatidylserine from the inner leaflet of the plasma membrane to the outer leaflet. The shrunken apoptotic cell, often referred to as an apoptotic body with its externally located phosphatidylserine, is recognized by macrophages, which phagocytose the apoptotic body and remove it from the tissue. With apoptosis there is minimal inflammation.

Necrosis occurs exclusively in pathological situations and represents a severe cellular response to injury [48,51,52]. The events of necrosis include mitochondrial swelling and dysfunction; rupture of the plasma membrane; and release of intracellular constituents to the extracellular space resulting in an acute inflammatory response.

The details and signaling mechanisms underlying apoptosis and necrosis have been intensively investigated using mostly cell lines [47,48,50–54]. In general, apoptosis in pancreatic tissue (acinar cells) as well as nonpancreatic tissues is mediated mainly by activation of a family of cysteine proteases called caspases. Caspases are synthesized as inactive precursors and are activated by cleavage induced by proteases including the caspases themselves. Caspases are divided into two major groups: the "effector," or "executioner," caspases, which are responsible for most of the cleavages that disassemble the cell; and "initiator" caspases, which trigger cleavage and activation of the "executioner" caspases. There is mitochondrial involvement in apoptosis as well. Stresses to the cell can act directly on the mitochondria or through initiator caspases to cause specific mitochondrial changes, including depolarization of the mitochondrial membrane potential, permeabilization of the outer mitochondrial membrane, and release of factors into the cytoplasm that interact with the caspase system (apoptogenic factors). A major mitochondrial apoptogenic factor is cytochrome c. Cholecystokinin-octapeptide at supraphysiological doses, tumor necrosis factor-α, and lipopolysaccharide have been shown to cause apoptosis of pancreatic acinar cells in vitro [18,38,48,55–57]. Of note, proteins of the Bcl-2 family regulate mitochondrial permeability [47,50,58–60]. Some, such as Bcl-2 and Bcl-xL, inhibit mitochondrial permeability, whereas others, such as Bax, Bak, Bad, Bid, and Bcl-xS, enhance permeability. Although roles for these regulators in the mechanism of cell death in acute pancreatitis remain largely unknown, there is upregulation of Bcl-xL and Bax in the pancreas during acute pancreatitis [61,62].

There is a general consensus that the level of ATP in the cell can determine whether a cell will die by apoptosis or necrosis [48,63–66]. That is, with a given stimulus for cell

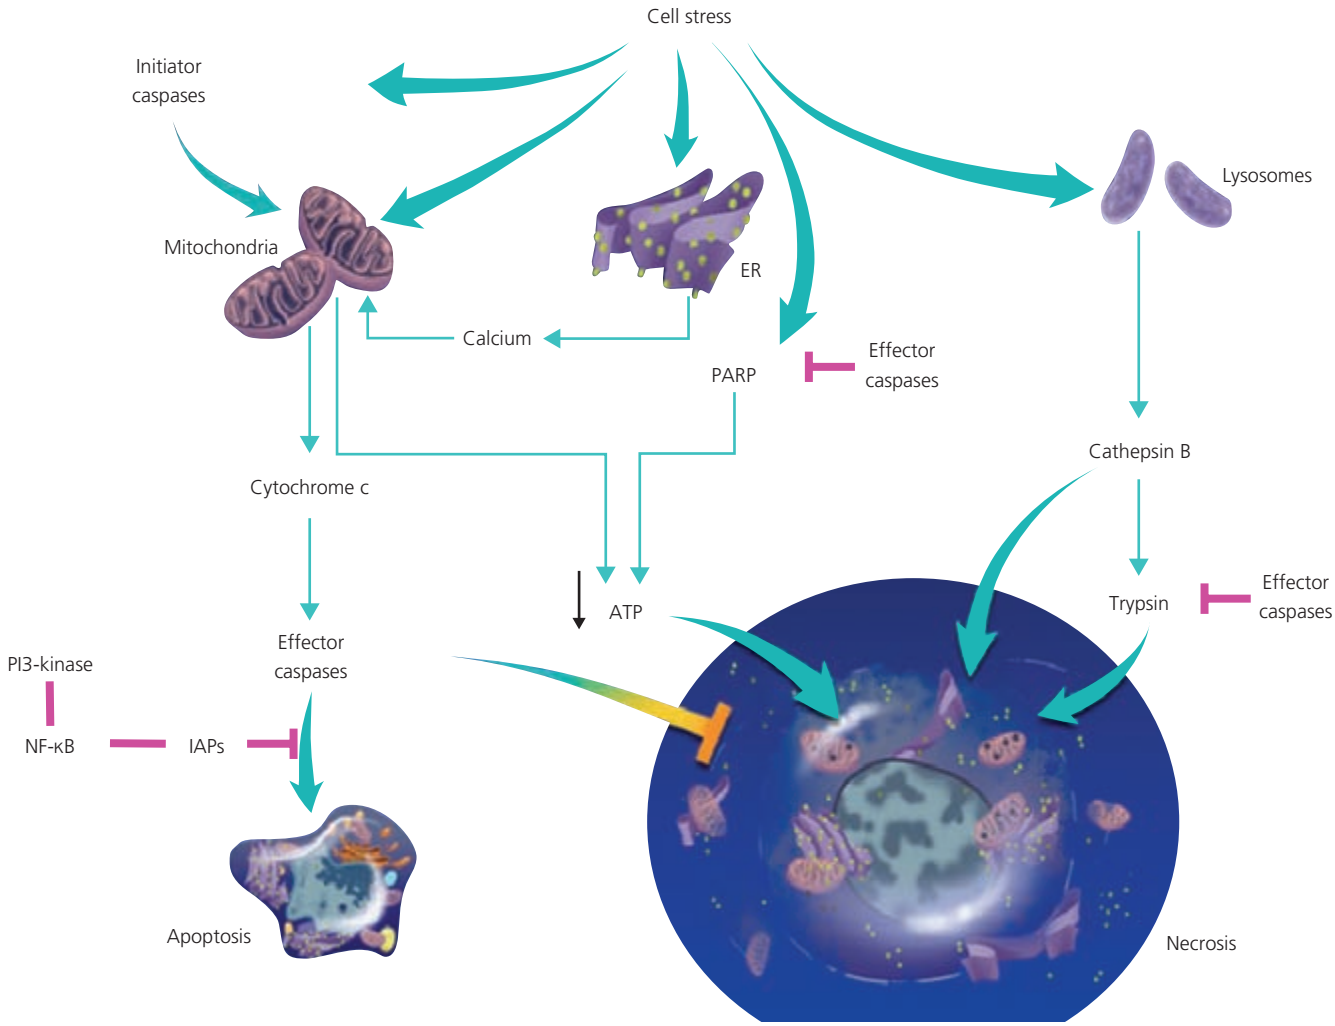

Figure 68.6 Cell death pathways in acute pancreatitis, showing the interrelationship between apoptosis and necrosis pathways and various regulatory systems that may alter the outcome of cell death. In addition to caspase and mitochondrial pathways mediating cell death, endoplasmic reticulum (ER) stress pathways can mediate cell death, at least in part, through release of its stored calcium, which can activate mitochondrial death pathways. Lysosomal pathways are involved through their cathepsins, which can mediate cell death in many tissues. In the pancreas, cathepsins can also activate digestive enzymes in the cell, which can augment cell damage. Severe mitochondrial dysfunction can lead to ATP depletion, and this deenergization of the cell can lead to necrosis. In this case, apoptosis will not occur because ATP is necessary for the activation of effector caspases. As shown, the enzyme poly(ADP-ribose) polymerase (PARP) is upregulated in cell injury; it uses ATP in performing DNA repair, thereby depleting ATP further increasing cell vulnerability to necrosis. Phosphatidylinositol 3-kinase (PI3-kinase), nuclear factor-κB (NF-κB), and inhibitors of apoptosis (IAPs) can inhibit apoptosis, a mechanism of importance in cancer as well as pancreatitis. This inhibitory system represents one pathway for cancer cell resistance to death. Finally, effector caspases can have several effects that modulate the cell injury and death response. Adapted from Sawicki et al. [313], with permission. Copyright, American Gastroenterological Association Institute, Bethesda, MD.

injury, greater levels of ATP depletion will result in necrosis whereas lesser amounts of ATP depletion will result in apoptosis. Because mitochondria are the principal generators of ATP production, necrosis results when mitochondrial injury is greater. One reason why low levels of ATP lead to necrosis is that ATP is necessary for key steps in the caspase pathway. If the caspase pathways and apoptosis are blocked the cell will likely proceed to necrosis. Another important aspect of ATP is that it is necessary for maintaining ion pumps that are essential for cell integrity [48,63–66]. Thus, mitochondrial function is a key arbiter of cell injury. Another pathway that mediates cellular ATP depletion involves the nuclear enzyme, poly(ADP-ribose) polymerase (PARP). This enzyme catalyzes polyADP-ribosylation of DNA-binding proteins such as histones and is involved in DNA repair [67,68]. Breaks in DNA activate PARP, and excessive activation results in ATP depletion because ATP is needed to replenish NAD^+, the substrate for PARP [69,70]. The importance of PARP in acute pancreatitis comes from studies in experimental models demonstrating that PARP activity markedly increases

during acute pancreatitis and pharmacological blockade of PARP decreases necrosis [71,72].

As illustrated in Fig. 68.5, there are several other potential inputs that can determine the type of cell death during pancreatitis, both dependent and independent of mitochondria and ATP. These include release of calcium from the endoplasmic reticulum, which in turn can lead to mitochondrial dysfunction [73–77]; lysosomes and their content of cathepsin B, which can mediate intracellular activation of digestive enzymes such as trypsinogen [78,79]; and intracellular signaling systems such as NF-κB and phosphatidylinositol (PI) 3-kinase, which can regulate expression of proteins that can inhibit apoptosis and thus promote necrosis. The proteins that inhibit apoptosis are called inhibitors of apoptosis (IAPs). Studies in experimental models have shown that activators of apoptosis decrease the severity of pancreatitis, suggesting that manipulating pathways that promote apoptosis during acute pancreatitis might decrease necrosis and the severity of the disease and thus improve outcome [18,48,80,81]. For example, alcohol feeding in rats has been demonstrated to decrease the expression of caspases in the pancreas and thus may reduce apoptosis and enhance necrosis [82,83]. This effect of alcohol may explain why alcohol represents the major risk factor for pancreatic necrosis [84]. Further, alcohol is metabolized in the pancreas to FAEEs, which have been shown to release calcium from endoplasmic reticulum stores, resulting in mitochondrial uptake, ATP depletion, and necrosis [31,85–87].

Experimental models of acute pancreatitis indicate that there is a close interaction between inflammation and cell death response, as depicted in Fig. 68.4 [37,38,45,88]. Removal of neutrophils from animals during experimental pancreatitis markedly decreases pancreatic necrosis and the severity of pancreatitis while increasing pancreatic apoptosis. The effect of neutrophils is likely mediated by both their production of reactive oxygen species and secretion of elastase [37,89]. Further, inhibition of intracellular inflammatory signaling in acinar cells by inhibition of NF-κB activation results in increased caspase activity and apoptosis in the pancreas during experimental pancreatitis [45]. The inflammatory response also increases intracellular activation of digestive enzymes suggesting possible relationships between the inflammatory response, digestive enzyme activation, and necrosis [37]. The signaling mechanisms underlying the effect of the inflammatory response on cell death are not well understood but probably include regulation of expression of IAPs, which inhibit executioner caspase activation, because the expression of these inhibitors is regulated by NF-κB activation [90–93]. Further, inhibitors of PI3-kinase may have an effect on IAPs because of the known ability of PI3-kinase to activate NF-κB [94]. Inhibition of both NF-κB and PI3-kinase activation have been demonstrated to decrease pancreatitis severity in pancreatitis models [95,96]. The importance of understanding the regulation of cell death by the inflammatory response comes from clinical observations that necrosis develops a few days after the initiation of acute pancreatitis when inflammation is the predominant process [21]. Thus, treatments designed to attenuate inflammation in pancreatitis will have the secondary benefit of decreasing necrosis.

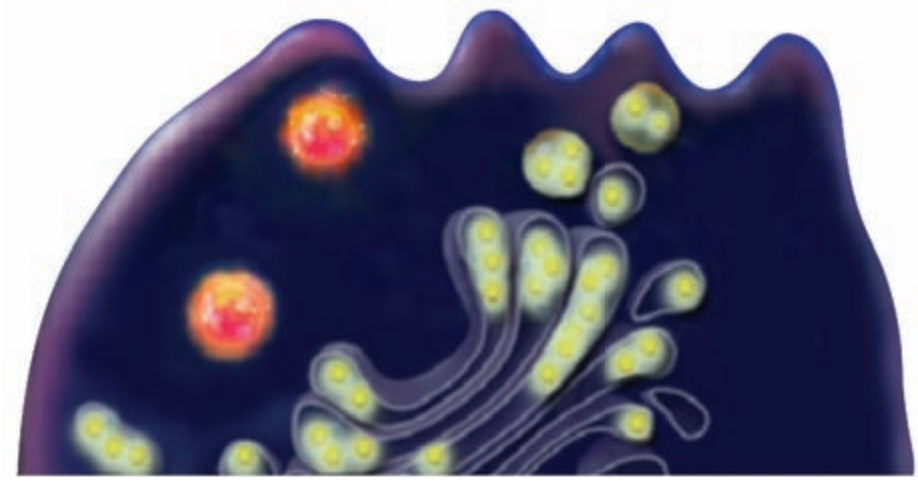
Intracellular activation of digestive enzymes

Intracellular digestive enzyme activation represents an early event in the course of both experimental and human pancreatitis [97]. In the normal state, the pancreatic acinar cell protects itself from the potential damaging effects of the digestive enzymes by several mechanisms, as listed in Fig. 68.7. More specifically, many of the digestive enzymes are synthesized and stored in zymogen granules as inactive proenzymes. Such proenzymes include trypsinogen, chymotrypsinogen, procarboxypeptidases, proelastase, and prophospholipases. In normal physiology, these proteins are delivered to the duodenum, where the brush border enzyme enterokinase cleaves an amino-terminal portion of the trypsinogen molecule resulting in an "opening" of the catalytic site of trypsin. Trypsin then catalyzes the activation of the other proenzymes and autocatalyzes activation of itself.

In contrast to normal physiology, in pancreatitis there is activation of the proenzymes in the pancreatic acinar cell. The importance of intracellular digestive enzyme activation is underscored by findings that mutations in the trypsinogen gene lead to a form of hereditary pancreatitis [98,99]. The mutations cause an increase in activated trypsin in the pancreatic acinar cell because of changes in protein folding that reduce the interaction of trypsin with pancreatic trypsin inhibitor resulting in decreased degradation and increased accumulation of active trypsin. In addition, there are mutations in the pancreatic trypsin inhibitor that also appear to be predisposed to developing pancreatitis [100].

The mechanisms of intracellular digestive activation, including the location within the cell where this occurs, are under intensive investigation. The prevailing hypothesis is that activation is a result of abnormal sorting of lysosomal cathepsin B and digestive enzymes into a common compartment [101]. There cathepsin B converts trypsinogen into trypsin. Trypsin then catalyzes the activation of itself and other zymogens as happens in the intestine with enterokinase. Support for this hypothesis comes from experiments showing that genetic and pharmacological inhibition of cathepsin B decreases activation of intracellular trypsinogen and the severity of pancreatitis in experimental models of pancreatitis [78,79,102]. There is also a line of work suggesting a key role for proelastase conversion to active elastase independent of trypsinogen activation [103,104].

Digestive enzyme conversion takes place in vacuoles that develop in the apical portion of the pancreatic acinar cell during experimental pancreatitis [37,105,106]. The mechanism of formation of these vacuoles, which is promoted by ethanol feeding and the inflammatory response, is also under investigation [37,107].



- Synthesis of enyzmes as inactive zymogens
- Trypsin inhibitor packaged in zymogen granule
- Segregation of enzymes in membrane-bound compartments
- Enterokinase restricted to small intestine

Figure 68.7 Protective mechanisms in the pancreas. The cartoon indicates zymogens that have been pathologically activated in an acinar cell. Listed are the protective mechanisms present in the pancreas to prevent activation of zymogens in the pancreatic cell and thus prevent the damaging effects of zymogen activation. Adapted from Gorelick et al. [312], with permission. Copyright, American Gastroenterological Association Institute, Bethesda, MD.

Inhibition of secretion

A common feature of many experimental models of pancreatitis is inhibition of enzyme secretion from the pancreas. This is likely to be due to derangements of the apical actin cytoskeleton or the SNARE protein machinery responsible for exocytosis at the apical pole of the acinar cell [108–110]. Inhibition of secretion may lead to pancreatitis because it prevents removal of activated intracellular enzymes from the cell [111].

Vascular response

The role of vascular responses in determining the severity of acute pancreatitis in humans is underscored by a report from Sendai, Japan [21]. A long-term (1988–2003) study in Japan showed significant vascular changes occurring early in the course of cases that went on to develop severe necrotizing pancreatitis. Specifically, the investigators compared early angiographic abnormalities with subsequent contrast-enhanced computed tomography (CE-CT) studies during the course of pancreatitis. The remarkable finding was a high incidence of vasospasm detected by angiography (both intrapancreatic and extrapancreatic) occurring in patients who went on to have necrotizing pancreatitis. Furthermore, the areas of necrosis as detected by CE-CT over subsequent days occurred in regions downstream of the vasospasms observed early in the course with angiography.

The microvascular circulation is also significantly affected in acute pancreatitis. Studies of microcirculation of the exocrine pancreas show that in the normal pancreas, the acinus is surrounded by a large number of small capillaries that form a network around the acinus [112,113]. With the onset of experimental pancreatitis there are a number of changes in the microvascular circulation; these include increased and homogeneous microperfusion in mild edematous pancreatitis; increased vascular permeability and edema formation; and a progressive decrease in capillary perfusion despite stable hemodynamics in necrotizing pancreatitis [21,112–120]. The decreased microperfusion is generally considered to be a key underlying event leading to necrosis.

In addition to the perfusion changes, the microvasculature plays an essential role in the inflammatory response [120–122]. That is, the inflammatory response requires the participation of postcapillary venules, where the expression of adhesion molecules such as ICAM-1 results in adhesion and migration of leukocytes from the intravascular space into the parenchyma. Regulation of the vascular responses is less well understood and likely involves several participants including endothelin-1, several cytokines/chemokines, and endothelial nitric oxide synthase [123–129].

Neural input

The role of neural inputs in the genesis of acute experimental pancreatitis has been demonstrated in a number of animal studies. It was reported that in experimental pancreatitis several factors activate the transient receptor potential vanilloid-1 (TRPV-1) in the pancreas. The activation of these receptors stimulates release of substance P and calcitonin gene-related peptide (CGRP) from neural endings, which in turn mediate the development of pancreatitis [130–135].

Specific etiologies

Knowledge of the cause of acute pancreatitis may guide treatment and allow prevention of further episodes. Many patients have an easily identifiable and treatable cause such

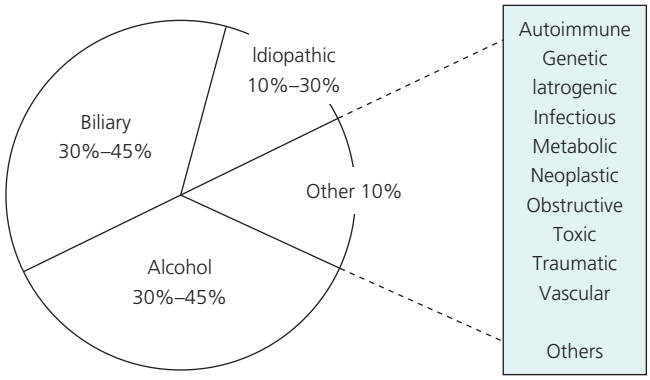


Figure 68.8 Etiologies of acute pancreatitis.

as gallstones or hyperlipidemia. Less common causes should be considered in those with no obvious precipitant, especially in patients with recurrent, unexplained bouts of pancreatitis. An overview of various etiologies is shown in Fig. 68.8.

Obstructive

Many forms of pancreatic duct obstruction have been associated with pancreatitis, including gallstones, sphincter of Oddi stenosis, ampullary or pancreatic tumors, pancreas divisum, duodenal diverticula, annular pancreas, and parasites, clots, or foreign bodies lodged in the ampulla. Gallstones are the commonest cause of acute pancreatitis in many parts of the world.

Gallstones

Pancreatitis develops in only a small percentage of patients with gallstones. In a cohort of persons with gallstones followed longitudinally, the incidence of acute pancreatitis was 0.17% per year [136]. The presence of gallstones, however, increases the relative risk for acute pancreatitis 14- to 35-fold in men and 12- to 25-fold in women [137]. The presence of small gallstones (< 5 mm), a larger cystic duct, and a long common channel in the ampulla all predispose to gallstone pancreatitis. Metabolic factors also may increase the risk for development of pancreatitis from gallstones. For example, underlying hyperlipidemia manifest by delayed chylomicron clearance may make patients more susceptible to gallstone pancreatitis [138].

Over a century ago, on the basis of autopsy findings, Opie proposed that a gallstone obstructing the ampullary orifice causes pancreatitis by promoting reflux of bile into the pancreatic duct through the common channel. Several observations have challenged that theory: patients without a common channel can have gallstone pancreatitis [139], and retrograde flow of bile into the pancreatic duct at physiological pressures does not induce pancreatitis in animals [140].

Opie also proposed that pancreatic duct obstruction alone might be the mechanism by which stones cause pancreatitis. In general, simple obstruction of the pancreatic duct in animals has not generated pancreatitis. In the American opossum, however, pancreatic duct obstruction alone does generate acute pancreatitis [141]. This animal model supports the "ductal obstruction theory," as does the occurrence of human pancreatitis in other forms of pancreatic duct obstruction.

Most biliary pancreatitis is precipitated by the transient or persistent obstruction of the papilla by a stone. When patients are selected based on hyperbilirubinemia and pancreatitis, gallstones can be recovered from the stool in up to 85% [142], proving that pancreatitis is usually accompanied by passage of a gallstone into the lumen of the intestinal tract. Stone passage into the duodenal lumen probably occurs on the first day of the attack in most patients with gallstone pancreatitis, and in many patients it may already have occurred by the time the patient reaches the hospital emergency department. Persistence of stones in the bile duct or ampulla is associated with more severe disease [143,144].

If gallstones predispose to acute pancreatitis, removal of the gallbladder should decrease the risk. In one large series, cholecystectomy in patients without a history of acute pancreatitis reduced the risk for the subsequent development of pancreatitis at least 10- to 20-fold [136]. Despite the increased risk for development of acute pancreatitis in those with gallstones and the success of cholecystectomy in decreasing the risk, the incidence of the disease is too low to warrant prophylactic cholecystectomy in patients with asymptomatic gallstones.

Microlithiasis

Crystals or aggregates of crystals in bile, referred to as microlithiasis, may cause recurrent bouts of pancreatitis in the absence of gallstones [145,146]. In some series microlithiasis is a leading cause of otherwise unexplained acute pancreatitis.

Microlithiasis may be identified during abdominal or endoscopic ultrasound as amorphous, layering, nonshadowing material (sludge) or brightly echogenic cholesterol crystals within the gallbladder (Fig. 68.9). Sonographically apparent sludge may be associated with prolonged fasting, rapid weight loss, total parenteral nutrition, gastric surgery, and administration of some drugs including octreotide and ceftriaxone.

Microlithiasis can also be diagnosed by examining bile for birefringent cholesterol monohydrate crystals or reddish brown calcium bilirubinate granules. Bile for microscopy can be obtained from the bile duct during endoscopic retrograde pancreatography (ERCP) or aspirated from the duodenum after slow intravenous administration of cholecystokinin (CCK) octapeptide; dark gallbladder bile should be collected and examined. Endoscopic ultrasound may be more sensitive than bile microscopy for detection of cholesterol crystals in the gallbladder [147].

Crystals, like stones, cause pancreatitis that begins abruptly, often with an initial rise in serum levels of both pancreatic and liver enzymes. Several treatment modalities have been

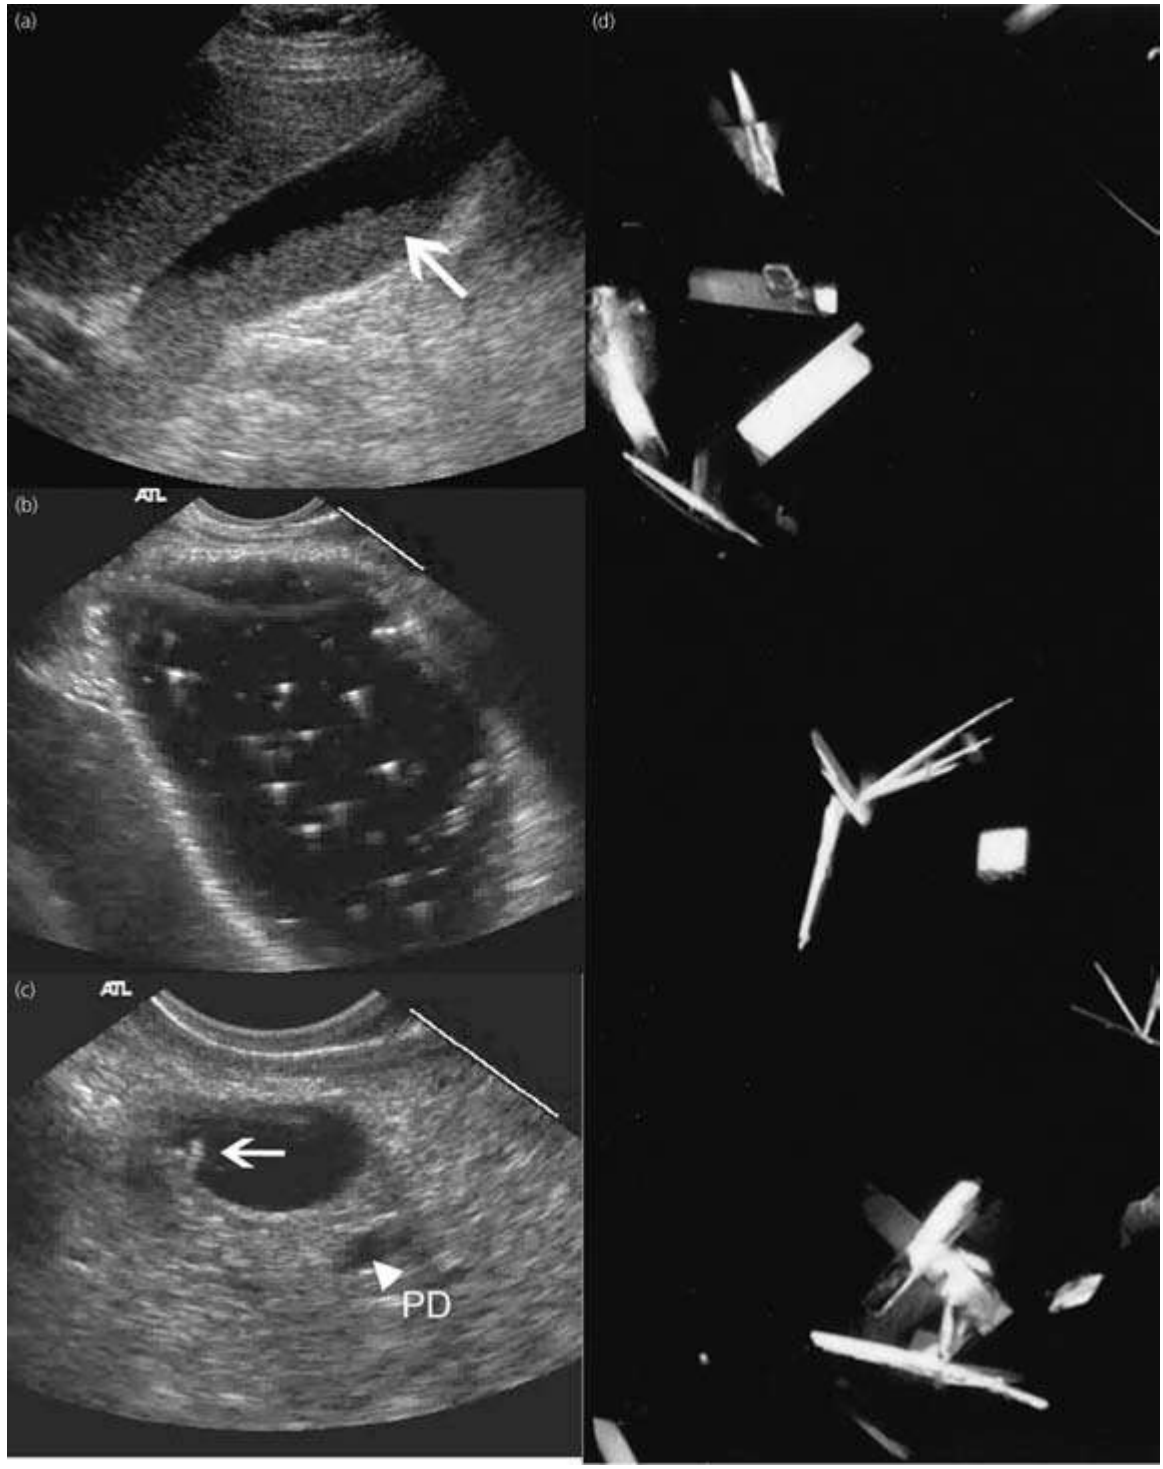

Figure 68.9 Biliary sludge and microlithiasis. **(a)** Transcutaneous ultrasound demonstrates gallbladder sludge (arrow). used, including ursodeoxycholic acid, cholecystectomy, or endoscopic sphincterotomy. Each form of intervention has been reported to reduce the frequency of attacks by at least two-thirds.

Stenosis and spasm of the sphincter of Oddi

The sphincter of Oddi is a complex muscular structure that regulates the flow of pancreatic secretions and bile into the duodenum. The sphincter acts as a variable resistor. Abnormalities of the sphincter have been identified in patients with recurrent abdominal pain after cholecystectomy, presenting with recurrent acute pancreatitis.

The biliary and pancreatic portions of the sphincter of Oddi are partly independent anatomically and functionally. Acting indirectly through inhibitory neural pathways, CCK causes both components of the sphincter to relax, facilitating the flow of bile and pancreatic juice into the duodenum after a meal. Cholecystokinin may also act directly on the sphincter and cause contraction [148]. This paradoxical dysfunction of the sphincter may occur after biliary tract surgery (perhaps because the innervation of the sphincter is interrupted), vagotomy, or gastric resection, and has been demonstrated to occur in both components of the sphincter after intravenous administration of CCK octapeptide to patients during sphincter of Oddi manometry.

Other secretagogues and transmitters including vasoactive intestinal peptide (VIP), glucagon, and nitric oxide also appear to mediate relaxation of the sphincter [149]. Secretin normally induces an initial increase in phasic contractions of the sphincter, followed by relaxation [150].

Obstruction to flow through the ampulla may be caused by dysfunction of the sphincter or by scarring and stenosis of the sphincter and the ampullary outlet. Stenosis of the sphincter is most commonly the result of previous trauma from stone passage, surgical manipulation, or endoscopic sphincterotomy, but may also be due to a primary inflammatory or fibrosing process in the ampulla of Vater. Stenosing papillitis may be caused by chronic pancreatitis, sclerosing cholangitis, or by opportunistic infections associated with AIDS. Sphincter dysfunction may be associated with medications (such as narcotics) and may possibly follow acute pancreatitis regardless of its etiology [151].

Criteria for the clinical diagnosis of sphincter of Oddi stenosis or dysfunction are well established for biliary sphincter disease, as described elsewhere in this text. The diagnosis and role of sphincter disease in pancreatitis is less clear. Pancreatic sphincter stenosis may be suspected in patients with a dilated pancreatic duct, poor pancreatic duct drainage (identified during ERCP or secretin-MRI), and difficulty in passing ERCP catheters through the papilla over a deeply placed pancreatic guidewire. Pancreatic sphincter hypertension can be identified using sphincter of Oddi manometry performed during ERCP. Manometric abnormalities of the pancreatic sphincter have been reported in a high percentage of patients with idiopathic recurrent pancreatitis [152]. The presence of stenosis or manometric sphincter abnormalities does not prove that these findings are the primary cause of pancreatitis. Limited, uncontrolled data suggest that surgical or endoscopic treatment of a hypertensive pancreatic sphincter prevents recurrent pancreatitis in some patients [153]. Endoscopic pancreatic sphincterotomy opens the pancreatic sphincter incompletely in many patients, and symptomatic stenosis of a pancreatic sphincterotomy or sphincteroplasty may occur in up to 25%. Stenosis may recur after treatment and can be difficult to treat effectively.

Alternatives to sphincter ablation are of unclear value in treating pancreatic sphincter hypertension. Medical therapy with calcium channel blockers or intraampullary botulinum toxin injections have been used in patients with biliary sphincter dysfunction and may be effective in pancreatic sphincter dysfunction as well. Pancreatic stenting has questionable utility as a therapeutic trial, because stents can cause pain in some patients, and may induce changes of chronic pancreatitis when left in place for more than a short time [154] despite advances in stent technology [155].

Pancreas divisum

During fetal development the dorsal and ventral pancreatic buds each form ducts that enter the duodenum. The ventral pancreatic bud rotates around the duodenum and fuses with the dorsal bud; typically the ducts within the buds join as well. The ventral duct drains the pancreas through the major papilla (duct of Wirsung) and the remnant opening of the dorsal duct forms the minor papilla (duct of Santorini). When fusion between the two ducts is partial or absent, the dorsal duct drains most of the pancreas through the minor papilla. This anatomical variant is known as pancreas divisum.

Pancreas divisum can be subdivided into complete divisum, in which the ventral and dorsal ducts do not communicate, and incomplete divisum, in which a diminutive duct joins ventral and dorsal pancreas, but the bulk of exocrine secretion still occurs through the minor papilla. In both situations there is dominant dorsal duct drainage.

The relationship of pancreas divisum to pancreatitis has been debated. Pancreas divisum is a common abnormality, with autopsy series reporting an incidence of about 5%. The incidence as assessed by ERCP ranges from 0.3% to 8%. This variability reflects differences in patient populations and definitions of the anomaly. For example, some studies include only patients with a complete separation between the dorsal and ventral ducts. Although an initial ERCP study reported that pancreas divisum was more common in patients with unexplained recurrent pancreatitis than in other patients undergoing ERCP, subsequent studies have not confirmed this association [156]. Proponents of the pathological association have suggested that resistance to the flow of secretions through the duct of Santorini causes ductal hypertension and pancreatitis. Studies of experimental

pancreatitis have shown that obstruction of the opossum pancreatic duct may result in pancreatitis [141]. Although the vast majority of individuals with pancreas divisum are asymptomatic, it is likely that a small number experience recurrent pancreatitis related to relative obstruction of the minor papilla. These may be individuals with a particularly diminutive minor papilla orifice.

Proposed diagnostic tests for minor papilla stenosis rely on pancreatic duct imaging before and after intravenous secretin administration. In normal persons the pancreatic duct dilates transiently after secretin is given, returning to within 1 mm of its baseline diameter within 15 min. In some persons with pancreas divisum prolonged ductal dilation following secretin administration has been demonstrated with transabdominal ultrasound, endoscopic ultrasound, or MRI [157–159]. Magnetic resonance imaging may also demonstrate a dilated terminus of the dorsal duct, or "Santorinicele," after secretin administration [158]. The bulk of available uncontrolled data suggests that prolonged ductal dilation after secretin administration, or appearance of a Santorinicele, is a predictor of response to endoscopic treatment of pancreas divisum.

Treatment studies also suggest that obstruction to flow through the minor papilla can cause pancreatitis. A small, blinded, randomized trial showed that endoscopic stenting of the minor papilla prevented recurrent pancreatitis when compared with sham therapy in patients with pancreas divisum [160]. A larger body of uncontrolled surgical and endoscopic experience supports this conclusion, and suggests that improved dorsal duct drainage is most likely to help patients with pancreas divisum and otherwise unexplained recurrent acute pancreatitis. Early studies indicated that 50%–70% of such patients will improve substantially after minor papilla sphincterotomy, although one report found that many patients who initially respond subsequently relapse [161]. Patients with chronic pancreatitis are less likely to respond, and those with chronic abdominal pain but no history of pancreatitis will have short- to medium-term symptomatic improvement only 30% of the time [162]. A randomized study of minor papilla sphincterotomy in patients with pain alone, reported in abstract only, did not show a statistically significant benefit from endoscopic therapy [163].

The major difficulty in patients with pancreas divisum is selecting those who will benefit from endoscopic treatment. In some, divisum is an incidental finding, and treatment will be of no benefit. Secretin-stimulated pancreatic duct imaging may be useful, as failure of the duct to dilate for more than 15 min following secretin administration may predict a lower likelihood of response to invasive therapy [158,159]. Cystic fibrosis transmembrane receptor (CFTR) mutations are more common in patients with pancreas divisum and idiopathic pancreatitis than in controls [164], and divisum patients with CFTR dysfunction may be less likely to respond to endoscopic interventions [165]. Endoscopic interventions are best reserved for those with otherwise unexplained recurrent acute pancreatitis, and are best avoided in patients with pain alone. Botulinum toxin injections into the minor papilla have been reported to predict response to endoscopic sphincterotomy in patients with divisum and recurrent pancreatitis [166].

Toxins

Alcohol

Alcoholic pancreatitis may present as an acute bout of pancreatitis. These episodes are not always associated with established, chronic, underlying pancreatic damage. In one series of patients who died of acute alcoholic pancreatitis, almost 40% demonstrated little histological evidence of chronic pancreatitis [167]. The incidence of pancreatitis is surprisingly low in alcoholic patients. Dreiling and Koller reported that among 100 alcoholic patients, clinical pancreatitis developed in only 5%, cirrhosis in 15%, both in 1%, and neither in 80% [168]. Although these data may underestimate the true prevalence of disease, they indicate that in addition to the amount of alcohol ingested, unknown genetic or environmental factors affect a person's susceptibility to disease.

Several mechanisms may contribute to the development of alcoholic pancreatitis. These include sphincter of Oddi spasm, obstruction of small ductules by proteinaceous plugs, and direct toxic and metabolic effects [169]. Moreover, alcohol has also been found to stimulate pancreatic secretion through cholinergic pathways. Some have proposed that the combination of alcohol-induced sphincter of Oddi spasm and stimulated secretion is responsible for pancreatitis. Chronic ethanol exposure may also sensitize the pancreas to other insults by effects on the production of proinflammatory cytokines; conversion of digestive enzymes to their activated forms; and activation of intracellular death pathways, as described earlier.

Ethanol may also change the concentration and composition of proteins secreted by the pancreas, resulting in the formation of protein plugs within small pancreatic ductules. The protein plugs may obstruct pancreatic ducts and promote pancreatitis. Increased viscosity and elevated protein concentrations found in pancreatic secretions from alcoholic patients are likely to contribute to plug formation. By forming a rigid, insoluble protein structure, specific secretory proteins such as lithostathine and glycoprotein-2 may contribute to the formation of these protein plugs and to stone formation [170]. The failure to alkalinize the acinar lumen in alcoholics may also contribute to plug and stone formation. Increased amounts of lysosomal enzymes and an increased trypsinogen:pancreatic trypsin inhibitor ratio have been reported in pancreatic juice from alcoholic patients.

Drugs

A variety of drugs have been associated with pancreatitis [171]. With few exceptions, the mechanisms of drug-induced disease are unknown and most are idiosyncratic reactions.

Table 68.2 Examples of drug-induced pancreatitis

Proven	Probable	Possible/questionable
L-Asparaginase	Protease inhibitors	Carbamazepine
Azathioprine	Acetaminophen	Corticosteroids
Didanosine	5-Aminosalicylic acid	Cimetidine
Estrogens	Ergotamine	Furadantin
ACE inhibitors	Furosemide	Metronidazole
6-Mecaptopurine	Isoniazid	Minocycline
Pentamidine	Procainamide	Piroxicam
Sulfasalazine	Rifampicin	Ranitidine
Valproate	Thiazides	Tetracycline

ACE, angiotensin-converting enzyme.

Most drug-induced pancreatitis occurs within 2 months of drug initiation or an increase in drug dose. Drug-induced pancreatitis may be classified by the certainty of its relationship to disease. Rechallenge is taken as the gold standard of proof, but such information is often unavailable. A partial listing of medications grouped according to probability that they cause pancreatitis is presented in Table 68.2.

Among immunosuppressants, azathioprine and its major metabolite, 6-mercaptopurine, are the chief offenders; in one series of 396 patients taking these medications, pancreatitis was induced in 3.3% [172]. Symptoms developed in all patients within the first month of therapy. Rechallenge with either azathioprine or 6-mercaptopurine was invariably associated with a rapid recurrence of pancreatitis. Furthermore, attempts to desensitize with slowly increasing doses of 6-mercaptopurine were unsuccessful. Both cyclosporine (ciclosporin) and tacrolimus have been rarely associated with acute pancreatitis. The rare (~ 2%) but severe (~ 50% mortality) pancreatitis associated with renal or liver transplantation may be linked to drug therapy or to infection.

Pancreatitis can also be caused by some antiinfectives. Tetracycline has been linked to pancreatitis in patients with fatty degeneration of the liver, particularly during pregnancy, but may also precipitate pancreatitis in the absence of underlying liver disease. Tetracycline pancreatitis may occur after years of administration. Trimethoprim–sulfamethoxazole can precipitate pancreatitis, albeit uncommonly. Intravenous or aerosolized pentamidine causes pancreatitis depending on the cumulative dose of the drug. Another cause of pancreatitis in patients with AIDS is the antiviral agent, 2′,3′-dideoxyinosine (DDI). The onset of DDI-associated pancreatitis is typically delayed for several months after the initiation of therapy. Although the mechanism of DDI-induced pancreatitis is unknown, patients with a previous history of pancreatitis and those with advanced infection seem to be at highest risk for this complication. Decreasing the dose of DDI reduces the incidence of this serious complication. Pancreatitis may be caused indirectly by HIV protease inhibitors by elevating serum triglyceride levels. Stavudine and lamivudine have also been associated with pancreatitis [173].

Antiinflammatory agents may cause pancreatitis. Included are sulfasalazine and, in a small number of patients, oral 5-aminosalicylic acid [174]. Early reports of corticosteroid-induced pancreatitis are difficult to interpret because most patients had other possible causes of disease. Corticosteroids may directly precipitate pancreatitis as demonstrated by rechallenge, but this appears to be a rare event [175].

Antihypertensives and diuretics are widely used and alhough the incidence of pancreatitis is low with these drugs, they constitute an important family of disease-producing agents. Included on the list are furosemide, thiazide diuretics, and angiotensin-converting enzyme (ACE) inhibitors. A few agents induce metabolic abnormalities that predispose to pancreatitis. For example, therapy with estrogens or the retinoid derivative, isotretinoin, is associated with a dose-dependent increase in triglycerides and pancreatitis [176].

Agents that overstimulate neural pathways may cause acute pancreatitis. In animal models, neural stimulation can initiate pancreatitis or augment the disease caused by other agents. Parathion, an alkylphosphate cholinesterase inhibitor, is a widely applied agricultural insecticide. Ingestion or absorption of parathion through the skin may induce injury. Almost 50% of patients with toxic exposure to this agent will exhibit biochemical evidence of pancreatitis. Although parathion-induced pancreatitis is usually mild, fatal hemorrhagic pancreatitis has been reported. Acting through neural pathways, ergotamine poisoning decreases blood flow and may cause ischemic pancreatitis and hepatitis [177].

Scorpion venom

The venom of the scorpions *Tityus trinitatis* and *T. serrulatus*, found in Trinidad and Brazil, respectively, may induce a form of hyperstimulation pancreatitis. The toxic polypeptides in tityustoxin, acting through cholinergic pathways, are potent stimulants of pancreatic secretion in vitro and induce pancreatitis in animals [178]. In addition to causing pathological enzyme activation, tityustoxin may stimulate pancreatic secretion, induce sphincter of Oddi spasm, and alter blood flow.

Metabolic

Hyperlipidemia

Although hyperlipidemia may be caused by a bout of pancreatitis, it may also precipitate acute or chronic pancreatitis [179]. The breakdown products of triglycerides are probably responsible for inducing pancreatitis. When lipase in the pancreatic capillary bed acts on the high levels of triglycerides in serum, toxic free fatty acids are generated. The endothelial lining of small pancreatic blood vessels is the first site of injury. Damage of small blood vessels leads to recruitment of inflammatory cells and thrombosis. Hyperlipidemic pancreatitis may be associated with normal serum amylase determinations but elevated serum lipase levels.

Although triglyceride levels greater than 2000–3000 mg/dL usually are required for development of pancreatitis, a few patients seem to manifest this condition when serum levels are lower, and pancreatitis induced by intravenous lipid administration has been reported with serum triglyceride levels slightly greater than 500 mg/dL. In general, a level of greater than 1000 mg/dL should prompt suspicion of an underlying hyperlipidemic cause for pancreatitis. Some forms of hypertriglyceridemia show striking increases in serum triglycerides after a fatty meal, with lower values while fasting. It is important to measure serum triglycerides on the first serum sample obtained from a patient with otherwise unexplained pancreatitis. Measuring postprandial triglyceride levels after recovery may also be required to detect markedly elevated values.

In addition to patients with primary hyperlipidemia, elevated triglycerides may result from therapy with estrogen, retinoid derivatives, and HIV protease inhibitors. Typically, estrogen-related pancreatitis occurs within the first months following initiation of medication. Patients who are obese and have underlying glucose intolerance or fasting hypertriglyceridemia are at greater risk.

Treatment of acute hyperlipidemic pancreatitis includes standard supportive care. If parenteral nutrition is given, serum triglyceride levels should be monitored. Occasional patients with acute pancreatitis and severe hyperlipidemia (serum levels > 10 000 mg/dL) may benefit from plasmapheresis. Once the patient recovers from the acute symptoms, the cornerstone of therapy for hyperlipidemic pancreatitis is a low-fat diet. Attention must also be given to underlying diabetes or thyroid disease, as well as alcohol use, all of which can elevate serum triglycerides. In some cases, treatment with lipid-lowering drugs may be indicated.

Hypercalcemia

Experimentally, acute calcium infusion causes increased pancreatic duct permeability that may lead to a nonspecific increase in serum pancreatic enzyme levels. In animals, acute hypercalcemia may induce a mild form of pancreatic injury [180]. Virtually all causes of hypercalcemia, including hyperalimentation, infusions associated with cardiac bypass, immobilization, multiple myeloma, and hyperparathyroidism, have been linked to hyperamylasemia. These studies indicate that hypercalcemia is associated with an increase in serum enzymes, but probably causes pancreatitis infrequently and severe pancreatitis rarely.

Infectious

Viral including HIV/AIDS

The most common viral infections that may cause pancreatitis are mumps and Coxsackie B virus. These are self-limited and may account for lone bouts of pancreatitis. Viral hepatitis and fulminant hepatitis, especially hepatitis B, has been associated with pancreatitis. Influenza A and B, enterovirus, cytomegalovirus, and rubella may cause acute pancreatitis.

Hyperamylasemia has been reported in up to 40% of AIDS patients [181] and has remained common in the HAART (highly active antiretroviral therapy) era [173]. Clinical pancreatitis, however, probably occurs in less than 10% of all patients with AIDS, and in even fewer of those not receiving toxic medications. The diagnosis of pancreatitis should be based on bedside findings and imaging tests in combination with elevated enzyme levels, and not on the basis of elevated pancreatic enzymes alone. In addition to drugs and the other common causes of pancreatitis, at least three pathological processes contribute to pancreatitis in AIDS [173]:

- HIV may infect the pancreas, which may cause the elevated serum amylase often seen in AIDS, and may account for the changes of otherwise unexplained chronic pancreatitis that have been seen at autopsy of AIDS patients. However, HIV infection alone seems rarely to lead to clinical pancreatitis.
- Opportunistic infections may involve the pancreas. Most infections are caused by cytomegalovirus or *Mycobacterium avium*. *Cryptococcus*, *Toxoplasma gondii*, *Histoplasma*, *Mycobacterium tuberculosis*, and *Candida* species have been reported. Opportunistic infections involving the pancreas usually involve other organs as well. Although histological evidence of pancreatic opportunistic infection is common at autopsy, it is unusual for these opportunistic infections to produce clinical pancreatitis during life.
- Pancreatic neoplasms develop in up to 5% of patients with AIDS. Kaposi sarcoma and lymphoma are the most common and usually involve the pancreas in the setting of widely disseminated disease. Pancreatitis, however, is not a common manifestation of this tumor involvement.

Bacterial and parasitic

The list of bacteria associated with acute pancreatitis includes *Salmonella* species, *Shigella* species, *Campylobacter* species, hemorrhagic *Escherichia coli*, *Legionella* species, *Leptospira* species, and even *Brucella* species [182,183]. Pancreatitis associated with these infections is most likely secondary to released toxins. Usually, acute pancreatitis is not the primary manifestation of these infections. Direct involvement of the pancreas or ampulla with parasites is a common cause of pancreatitis in some populations. Almost 15% of cases of biliary pancreatitis in a series from the Orient could be ascribed to *Ascaris lumbricoides* infection [144]. Biliary and hepatic parasites, including *Fasciola hepatica* and *Clonorchis sinensis*, may also cause acute pancreatitis.

Autoimmune

Lymphoplasmacytic sclerosing pancreatitis

Lymphoplasmacytic sclerosing pancreatitis (LPSP), also called "autoimmune pancreatitis," has distinctive clinical, laboratory, imaging, and histological features (as shown in Fig. 68.10), and responds to corticosteroid therapy. Patients classically present with subacute symptoms of pancreatitis and frequently have obstructive jaundice; a minority present

with recurrent acute pancreatitis or pancreatic insufficiency. Some patients also have other autoimmune illnesses. Cross-sectional imaging in the acute phase of the illness may show a diffusely enlarged, "sausage-shaped" pancreas, or a focal pancreatic mass, usually without marked peripancreatic inflammatory changes. The gland may appear to have a capsule-like edge on CT or MRI, and there may be delayed enhancement with intravenous contrast [184]. Pancreatography classically shows diffuse irregular narrowing of the main pancreatic duct, but may also demonstrate a focal dominant pancreatic duct stricture simulating malignancy. Biliary involvement is not unusual, and may include strictures of the intrapancreatic bile duct, hilar strictures simulating malignancy, or intrahepatic ductal changes reminiscent of sclerosing cholangitis (Fig. 68.11). Histology shows a pathognomonic lymphoplasmacytic infiltrate involving small ducts and venules, and sparing arterioles; the inflammatory infiltrate stains positive for IgG4 (Fig. 68.10). Pancreatic calcification is uncommon.

A variety of laboratory abnormalities have been described, including elevated autoantibody levels and serum IgE concentrations, but the most characteristic laboratory findings appears to be an elevated serum IgG4 level [185], alone or together with generalized hypergammaglobulinemia. Elevations of serum IgG4 are present in about 75% of patients. Autoimmune pancreatitis may be one presentation of a systemic IgG4 disease, which can also manifest as retroperitoneal fibrosis, periaortitis, and biliary, ocular, or renal disease.

The differential diagnosis of autoimmune pancreatitis often includes pancreatic neoplasm. Patients may have involvement of adjacent vessels on cross-sectional imaging studies or new-onset hyperglycemia, further increasing the clinical suspicion of malignancy. Diagnostic criteria for autoimmune pancreatitis are debated; classically the diagnosis has been made on the basis of elevated serum IgG4 levels, diffuse pancreatic enlargement on CT or MRI, and diffuse narrowing and irregularity of the main pancreatic duct on pancreatography, but many patients do not have all of these findings. Elevation of the serum IgG4 is suggestive but not specific, as it has been reported in pancreatic malignancy. Other organ involvement is a useful clue in some patients. Intraductal brushings and biopsies obtained during ERCP, or endoscopic ultrasound (EUS)-guided needle aspiration of a mass are appropriate in some cases but generally do not establish a definite diagnosis of autoimmune pancreatitis. Endoscopic ultrasound-guided Tru-Cut biopsy of the pancreas can make the diagnosis by showing pathognomonic histological features, or suggestive histological features together with an IgG4-positive inflammatory infiltrate (Fig. 68.10). Pancreatic biopsy is appropriate in some patients, particularly if pathognomonic histology will prevent pancreatic resection. A key feature of the disease is the good response to oral glucocorticoids with resolution of pancreatic swelling and biliary obstruction, and a decrease in IgG4 levels [185]. Impaired pancreatic endocrine function may also improve [186]. Recurrence after a slow taper of oral steroids appears to be uncommon. The natural history of autoimmune pancreatitis is unclear, but some patients appear to develop subsequent pancreatic atrophy.

Inflammatory bowel disease

Pancreatitis in patients with inflammatory bowel disease may be related to drugs, structural and inflammatory changes, or may be idiopathic in nature. Most medications used for the treatment of inflammatory bowel disease have been reported to precipitate pancreatitis. This list includes azothioprine, 6-mercaptopurine, sulfasalazine, 5-aminosalicylic acid, and (rarely) corticosteroids. Sclerosing cholangitis is occasionally associated with clinical pancreatitis. This may be due to passage of small pigment stones through the ampulla, or to a sclerosing process affecting the pancreatic ducts as well as the bile ducts [187]. When pancreatic duct abnormalities are seen together with sclerosing cholangitis-like changes, the diagnosis of autoimmune pancreatitis should be considered.

Patients with pancreatitis and Crohn's disease may have inflammatory bowel disease of the duodenum. The inflammatory process may be associated with stenosis of the ampulla or a fistula into the pancreatic duct. The increased incidence of gallstones in patients with Crohn's disease should prompt a search for biliary causes of pancreatitis. In a small number of patients, however, no etiology is identified.

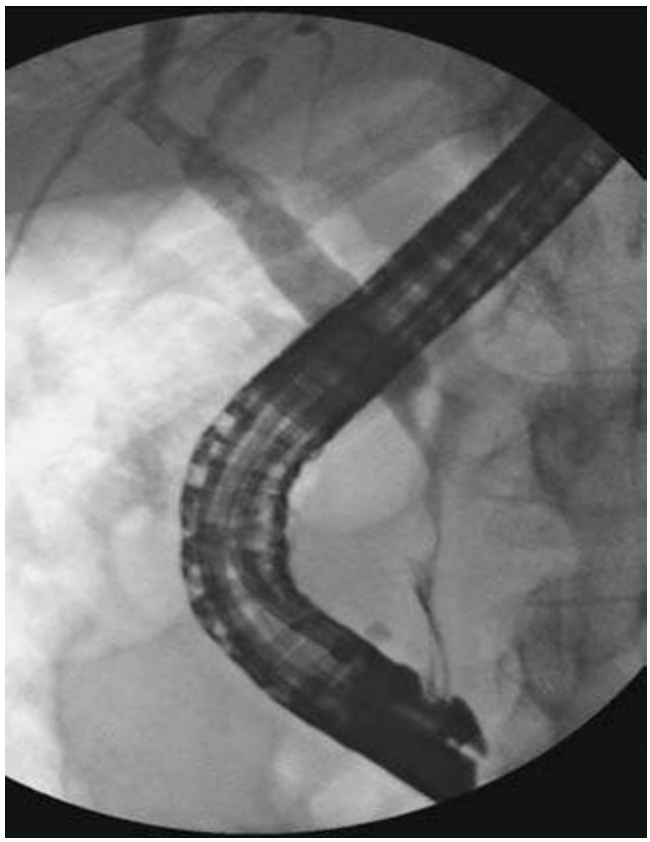
Systemic autoimmune diseases

Pancreatitis may occur in the setting of a systemic autoimmune disorder. Vasculitis affecting the pancreas has been described in systemic lupus erythematosus, periarteritis nodosa, Wegner disease, and Behçet disease. Pancreatitis may respond to successful treatment of the underlying vasculitis.

Genetic

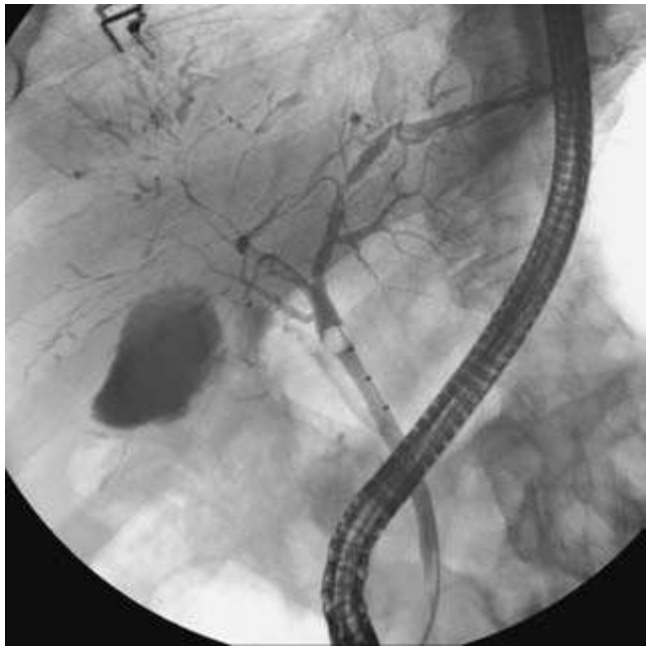
The best described form of familial pancreatitis is the autosomal dominant disorder known as hereditary pancreatitis. Penetrance approaches 80%. Affected family members have bouts of pancreatitis that often begin in childhood and typically progress to chronic pancreatitis (see Chapter 69). The course of the disease appears to be accelerated by alcohol. Many of these patients have been found to have mutations in the cationic trypsinogen (*PRSS1*) gene. The most common mutation (at Arg117) may make trypsin resistant to proteolytic degradation [98]. Patients with hereditary pancreatitis have a dramatically increased risk of pancreatic cancer [188]. Mutations in the pancreatic secretory trypsin inhibitor (*SPINK1*) gene also predispose to disease [189,190].

Mutations in the cystic fibrosis transmembrane regulator gene (*CFTR*) cause two patterns of pancreatic disease. First, classic cystic fibrosis results in pulmonary disease and pancreatic insufficiency, but rarely pancreatitis. These patients have elevated sweat chloride levels and markedly diminished



(a)

(b)



(c)

CFTR function in the nasal mucosa. Second, a pancreatitic phenotype is recognized that is not associated with pulmonary disease but can likely cause both acute and chronic pancreatitis [191,192]. These patients have normal sweat chloride values, and the CFTR function in the nasal mucosa is diminished but present. Although these patients exhibit mutations in the *CFTR* gene, they are not homozygous for the mutations that result in classic cystic fibrosis. Partial loss of CFTR function has been associated with other adult-onset, single-organ diseases. The prevalence of CFTR-related dis-

ease in patients with idiopathic pancreatitis and divisum-associated pancreatitis appears to be increased compared with that in the general population. Thes contribution of CFTR-related disease to alcoholic pancreatitis remains unclear.

Iatrogenic

Endoscopic retrograde cholangiopancreatography (ERCP)

Acute pancreatitis is the commonest complication of ERCP. Prospective studies with careful patient follow-up report an incidence of about 5%. In most cases the pancreatitis is mild and resolves within several days; complications requiring surgery are infrequent. Diabetes can rarely result from an episode of severe post-ERCP pancreatitis, and deaths due to pancreatitis have been reported in 0.02% of patients undergoing the procedure.

The chance of developing post-ERCP pancreatitis varies depending on both patient-related and procedure-related factors. The skill and experience of the endoscopist also affect the chance of pancreatitis, with low case volume increasing the risk for the patient [193,194]. The risk of post-ERCP pancreatitis is substantially higher when the pancreatic duct is visualized [195]. The number and hydrostatic pressure of pancreatic duct injections are probably also important, as well as the volume of fluid injected. In one study, the administration of more than four pancreatic duct injections was associated with an increased risk. Acinarization (visualization of the pancreatic parenchyma with injected contrast) is associated with subsequent pancreatitis about one-third of the time. In addition to filling and overfilling of the pancreatic duct, pancreatic outflow obstruction due to ampullary edema or spasm is a likely contributor to post-ERCP pancreatitis. Repeated attempts at bile duct cannulation may cause postprocedure pancreatitis even in the absence of pancreatic duct cannulation [194]. Pancreatitis has been reported after percutaneous biliary drains are advanced through the ampulla into the duodenum, with no injection or manipulation of the pancreatic duct.

Endoscopic sphincterotomy further increases the risk of pancreatitis, and may do so both by thermal injury to the pancreas and by provoking ampullary edema. Pre-cut sphincterotomy appears to increase the risk in some centers, but not in others where this technique is used routinely. Sphincter of Oddi manometry has been thought to increase the risk; however, a large study of postsphincterotomy complications found that the performance of manometry did not affect the incidence of pancreatitis in patients with suspected sphincter of Oddi dysfunction [194].

Patient factors also affect the chances of ERCP-induced pancreatitis. About 20% of patients with suspected sphincter of Oddi dysfunction undergoing sphincterotomy without prophylactic pancreatic duct stenting develop pancreatitis, and these patients may be at increased risk for severe pancreatitis. The risk is especially high in patients with small bile ducts [194]. Younger age and obesity probably also predispose to pancreatitis after ERCP. Conversely, patients with a chronically diseased or obstructed pancreatic duct appear to be at decreased risk for pancreatitis from ERCP.

The presence of acute biliary pancreatitis does not seem to increase the risk of the procedure. A history of contrast allergy has been reported not to increase the risk of post-ERCP pancreatitis, but many endoscopists favor pretreatment with steroids or use of nonionic contrast media in such patients [196]. Pretreatment may be especially important in patients with a history of serious allergic reactions to topical or ingested iodine.

Diagnosis

Symptoms of post-ERCP pancreatitis typically develop within 2–6 h of the procedure, although occasionally patients will first develop symptoms the following day. The presence of abdominal symptoms shortly after the procedure is a poor predictor of subsequent pancreatitis. Consensus criteria for diagnosis of pancreatitis after ERCP require elevation of serum amylase or lipase to three-fold the upper limit of normal on the day after the procedure, together with compatible clinical symptoms [196]. Early predictors of post-ERCP pancreatitis have been identified. Although elevation of the serum amylase is a nonspecific finding in the hours following ERCP, the height of amylase elevation may be useful. A normal serum amylase is a strong negative predictor of pancreatitis when measured 2 h after ERCP, at least in patients who have not received a prophylactic pancreatic duct stent [197].

Post-ERCP pancreatitis may occur even if the procedure is easily accomplished and all identified risk factors are avoided. Patients sent home after ERCP should be instructed to seek help promptly if pain or vomiting develop. It is our practice to use a clear liquid diet until the morning following ERCP to limit pancreatic stimulation in the postprocedure period.

Prevention

The best method of preventing ERCP-induced pancreatitis is to avoid ERCP when possible. Less invasive imaging modalities have decreased the need for diagnostic ERCP. When ERCP is required, both pharmacological and endoscopic strategies for the prevention of post-ERCP pancreatitis have been proposed. Some, such as use of low-osmolarity contrast media or pretreatment with calcium channel blockers, octreotide, aprotinin (a protease inhibitor), nifedipine, allopurinol, and IL-10, have proven to be ineffective. Reports of benefit from prophylactic diclofenac adminstration require larger, multicenter confirmatory studies [198].

Gabexate mesilate is a protease inhibitor that inhibits proteolytic activity of pancreatic enzymes. The few individual trials of gabexate for prevention of post-ERCP pancreatitis have all shown a benefit, although not statistically significant in most cases. A metaanalysis demonstrated a statistically significant benefit with gabexate pretreatment, which decreased the incidence of pancreatitis from 6.5% to 1.6%

[199]. Pretreatment of 27 patients would prevent one episode of pancreatitis. This agent is not licensed for use in the United States, and enthusiasm for gabexate has been tempered by its cost and its adminstration as a prolonged intravenous infusion.

Somatostatin also appears to decrease the incidence of post-ERCP pancreatitis. Numerous controlled trials of somatostatin have shown a benefit, often not statistically significant, but in metaanalysis a significant benefit was found [199]. Taken together, the incidence of pancreatitis was decreased from 13.5% to 5.6% in these studies. Pretreatment of 13 patients would prevent one episode of pancreatitis. Somatostatin appears to be effective when given either as a 12-h intravenous infusion or as a bolus intravenous injection immediately before cannulation of the papilla [200]. Somatostatin is not licensed for use in the United States. The lack of benefit of octreotide, a somatostatin analogue, may be due to its effects on sphincter of Oddi function and pancreatic blood flow.

Temporary pancreatic duct stenting dramatically decreases the risk of postsphincterotomy pancreatitis in some patients, including those with pancreatic sphincter hypertension or difficult biliary cannulation [201,202]. This finding highlights the usefulness of sphincter of Oddi manometry in patients with suspected sphincter dysfunction. However, a controlled trial of pancreatic duct stenting immediately after biliary sphincterotomy in a mixed group of patients did not show a reduction in postprocedure pancreatitis [203].

Postoperative

In the postoperative period there is an increase in the incidence of hyperamylasemia, even after extraabdominal procedures [204]. It appears that in many cases these increases in serum amylase levels are nonspecific and unrelated to clinically overt pancreatitis, although severe pancreatitis may ensue and can be related to hypotension, medication, or pancreatic trauma. In a prospective study, 32% of patients had hyperamylasemia after cardiac bypass, but only 2.7% had overt pancreatitis [205]. A direct correlation has been demonstrated between the elevation of pancreatic enzymes and the amount of calcium administered to patients during cardiac bypass, suggesting a nonspecific effect of calcium on pancreatic duct permeability. A severe form of pancreatitis sometimes does occur after cardiac bypass, and may be related to pancreatic ischemia.

Neoplastic

Pancreatitis is associated with both primary pancreatic tumors and metastases. In one series, 3% of patients with pancreatitis admitted to a university hospital were found to have pancreatic malignancy [206]. Pancreatitis has been reported in up to 10% of patients with pancreatic cancer, but it is usually mild [207]. Cancer can mimic chronic pancreatitis, presenting with a dilated pancreatic duct, or a pseudocyst that forms because of downstream ductal obstruction by the tumor. Cancer can also mimic acute pancreatitis, especially when bleeding into the pancreatic duct (hemosuccus pancreaticus) temporarily obstructs the duct. As clots pass through the papilla the serum liver enzymes may rise together with the amylase. Intraductal papillary mucinous neoplasm (IPMN) of the pancreas can similarly precipitate bouts of acute pancreatitis related to passage of mucus.

Frequently, symptoms of pancreatitis are associated with an early stage pancreatic neoplasm and may precede the diagnosis of pancreatic cancer by months. Older patients with unexplained pancreatitis should undergo a careful evaluation for occult malignancy (often including EUS), looking for a minute pancreatic cancer amenable to resection [208]. Positron emission tomography (PET) scanning may be useful for diagnosis of underlying pancreatic cancer in patients whose pancreatitis obscures a neoplastic mass on CT or EUS. Mature cystic lesions present on the patient's first CT scan may represent cystic neoplasms such as branch duct IPMN lesions rather than pseudocysts; EUS-guided fine-needle aspiration or Tru-Cut biopsy may be useful in differential diagnosis of such lesions.

Vascular

Ischemia is an uncommon cause of acute pancreatitis. Pancreatic infarcts may occur in patients with underlying atherosclerotic vascular disease, but are unusual because the pancreas is richly perfused from several different arterial sources. Cholesterol emboli may cause pancreatitis, cholecystitis, or bowel ulceration or infarction, and should be suspected when acute pancreatitis occurs after vascular interventions such as cardiac catheterization [209]. Patients may have associated evidence of renal, gut, or peripheral cholesterol emboli. Ischemic pancreatic and hepatic injury may be associated with malignant hypertension, low flow states due to severe heart failure, or administration of potent vasoconstrictors. Vasculitis may cause pancreatitis associated with systemic autoimmune diseases, as noted above.

Other

Trauma

Traumatic pancreatitis caused by penetrating or blunt injury is an important cause of disease in both adults and children. The symptoms of pancreatic trauma may be difficult to elicit in the severely ill patient and suspected only by the location of the injury. On occasion, recurrent bouts of pancreatitis may develop months to years after injury. The mid-pancreatic duct as it crosses the vertebral column is particularly susceptible to fracture from blunt trauma. In the acute setting, CT is useful in detecting a disrupted pancreatic duct, focal pancreatitis, and pancreatic necrosis (Fig. 68.12). Similarly, ERCP has been used to demonstrate persistent duct disruption, ductal stricture, and focal pancreatitis. Traumatic pancreatitis has been treated with stenting of the disrupted duct, pancreatic resection, or drainage [210].

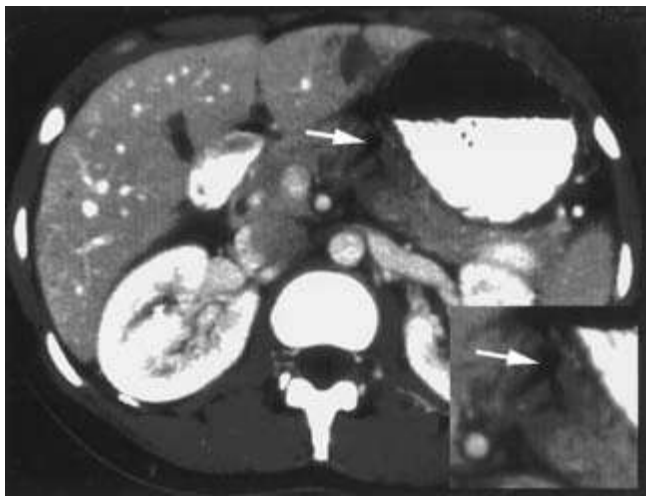

Figure 68.12 Traumatic pancreatitis. There is disruption of the pancreatic body anterior to the spine (arrow). The left lobe of the liver is also injured. Courtesy of Jeffrey Neitlich, Yale University.

Peptic ulcer

Ulcers located at the posterior duodenal bulb may penetrate into the head of the pancreas. Pancreatitis associated with duodenal ulcers is rarely severe and is usually not associated with dramatic increases in the serum amylase. This diagnosis should be considered in patients with ulcer disease when the typical epigastric burning pain of an ulcer begins to radiate to the back and is less responsive to ulcer medications.

Childhood

Pancreatitis may first present in childhood. Many cases of childhood pancreatitis are associated with multisystem disease such as sepsis, viral infections, hemolytic-uremic syndrome, and Reye syndrome. Blunt trauma caused by accidents or child abuse is the single most common cause of acute childhood pancreatitis, followed in decreasing order of incidence by congenital defects (including biliary cysts, anomalous pancreaticobiliary junctions, and pancreas divisum), metabolic diseases, and drugs. Children with hemolytic disorders such as sickle-cell anemia commonly form pigment stones in the gallbladder or bile ducts. Rarely, annular pancreas, duodenal diverticulum, ectopic pancreatic tissue, and duodenal duplication cysts may cause pancreatitis.

Miscellaneous

An increased incidence of pancreatitis has been reported during pregnancy and the early postpartum period. The increased incidence of hypertriglyceridemia and biliary stone formation during pregnancy may contribute to this predisposition. Thee is also an increased risk of acute pancreatitis reported in patients undergoing renal dialysis. The risk may be limited to those treated with chronic peritoneal dialysis and not hemodialysis [211]. Refeeding after long periods of fasting is said to precipitate pancreatitis, but this has not been well characterized. A few patients with possible food allergy-associated pancreatitis have been reported [212].

Idiopathic

The number of patients having unexplained bouts of pancreatitis has diminished in large part because of improvements in imaging tests and greater insight into genetic abnormalities in unexplained pancreatitis. The compelling evidence that biliary microlithiasis causes pancreatitis, the recognition of autoimmune pancreatitis, as well as the wider use of ERCP, EUS, and genetic testing, have further decreased the size of the idiopathic group.

Approach to unexplained pancreatitis

In 10%–20% of patients, pancreatitis is idiopathic despite careful evaluation of the history and physical exam, routine laboratory tests, transabdominal ultrasound, and CT. An etiological diagnosis can be made in most of these patients with further evaluation. A thorough diagnostic approach should be taken, including use of the medical history, physical examination, laboratory tests, and additional imaging studies. An algorithm outlining a general approach to such patients is shown in Fig. 68.13.

The patient's history should be reviewed, particularly with regard to alcohol and medication use, family history of pancreatic disease, and prior abdominal trauma. A history of male infertility or the physical examination finding of testicular atrophy may raise the possibility of congenital absence of the vas deferens, which is associated with decreased CFTR function and may signal a genetic basis for pancreatitis. Metabolic disease should also be considered. Serum triglycerides decrease with fasting, and a hyperlipidemic cause of pancreatitis may be missed if triglycerides were not measured soon after the patient's symptoms began. Hypercalcemia may not be apparent until after the patient has recovered from pancreatitis, because acute pancreatitis often lowers serum calcium levels.

Repeat abdominal imaging studies may be indicated in unexplained pancreatitis, as the quality of imaging studies may vary significantly based on the equipment used, the operator, the acuity of illness at the time the study was performed, and the use and timing of intravenous contrast. In addition, gallbladder sludge can come and go on serial abdominal ultrasound exams.

When there is evidence of chronic pancreatitis in the absence of alcohol use or familial pancreatitis, further evaluation can include laboratory tests for α_1-antitrypsin deficiency and hemochromatosis. Mutations of the *PRSS1* or *SPINK1* genes associated with hereditary pancreatitis may be present without a family history of pancreatitis as a result of a new mutation or low penetrance. Patients with *CFTR* mutations and pancreatitis usually do not have a family history of disease. Genetic testing for these disorders can be performed;

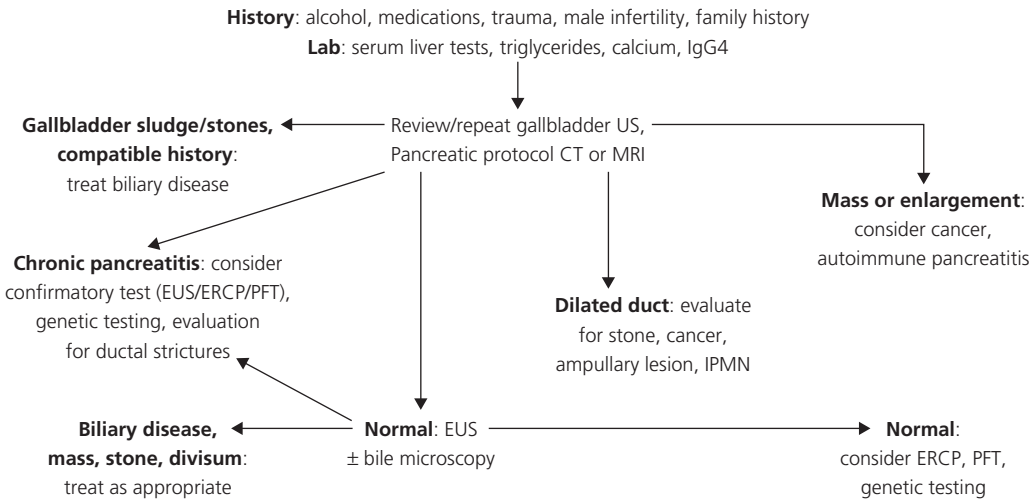

Figure 68.13 Algorithmic approach to unexplained pancreatitis. CT, computed tomography; ERCP, endoscopic retrograde cholangiopancreatography; EUS, endoscopic ultrasound; IPMN, intraductal papillary mucinous neoplasm; MR, magnetic resonance (imaging); PFT, pancreatic function test; US, ultrasound.

however, enthusiasm for this testing must be tempered by the absence of effective specific therapy, the lack of effective pancreatic cancer screening for patients with hereditary pancreatitis, and the possible psychological and insurability problems that may arise from the diagnosis of a genetic disorder. Genetic diagnosis may nevertheless be desirable, particularly for patients of child-bearing potential. In general it is wise to refer the patient for genetic counseling before obtaining these tests.

Biliary microlithiasis is a leading cause of recurrent acute pancreatitis and should be actively pursued in patients with unexplained disease. Endoscopic ultrasound and bile microscopy appear to play a complementary role in diagnosis, and microlithiasis is unlikely if both of these investigations are negative. Nevertheless, empirical cholecystectomy may be a reasonable option in some patients, especially if the clinical features of their acute attacks suggest a biliary source, and ampullary disease has been excluded.

Abnormalities of pancreatic duct drainage, including pancreas divisum, ampullary lesions, and sphincter of Oddi dysfunction, should be excluded in patients with recurrent acute attacks and no evidence of microlithiasis. Whereas EUS can diagnose ampullary masses and divisum, ERCP is particularly useful for diagnosis of sphincter dysfunction and incomplete divisum, in which the dorsal and ventral ducts communicate but dominant drainage is through the minor papilla. Such patients may present with recurrent mild pancreatitis [213]. Endoscopic retrograde cholangiopancreatography is also useful for diagnosis of intraductal papillary mucinous neoplasms of the pancreas, which often present with pancreatic symptoms and serum enzyme elevations. It may miss branch duct IPMN lesions, however.

It is generally our practice to use EUS instead of ERCP as the first endoscopic test in unexplained pancreatitis. Endoscopic ultrasound is particularly useful in patients with intact gallbladders, who may have microlithiasis, and in those over 40 years old, in whom the possibility of an early pancreatic malignancy or IPMN should be considered. Missed chronic pancreatitis, pancreas divisum, and ampullary lesions can be diagnosed during EUS as well. A diagnosis is made by EUS in about two-thirds of patients [214]. When disease remains idiopathic and is recurrent, ERCP (with the capability to perform sphincter of Oddi manometry) or a pancreatic function test (for diagnosis of chronic pancreatitis) can be pursued.

Diagnosis

The diagnosis of acute pancreatitis is almost always based on the presence of severe abdominal pain together with biochemical evidence of pancreatic injury. Rarely, patients with severe acute pancreatitis present without complaints of abdominal pain, but with respiratory failure or changes in mental status. The diagnosis of pancreatitis may be missed entirely when organ failure dominates the clinical picture. For example, in studies published during the 1980s, fatal pancreatitis went undetected until postmortem in 22%–42% of cases.

Symptoms

Pain is the most common symptom of acute pancreatitis and occurs in 95% of patients. It is often located in the epigastric and umbilical region and may radiate to the low thoracic region of the back. The pain usually does not reach its peak for 30 minutes to several hours and may last for hours to days. This deep, visceral pain is among the most severe and often leaves even the medicated patient in discomfort. In some, pain will decrease when sitting and leaning forward or

curling up on the left side, compared with lying flat. This finding is due to the retroperitoneal position of the pancreas and may be produced by other retroperitoneal processes. Nausea and vomiting are present in 85% of patients and may occur without an ileus or gastric outlet obstruction. Unlike patients with ulcer disease, vomiting does not relieve pain.

Signs

Low-grade fevers are reported in 60% of patients, and high-grade fevers may indicate the presence of cholangitis or either sterile or infected necrosis. Tachycardia and hypotension are found in up to 40% of patients and may result from intravascular volume depletion, enhanced vascular permeability, vasodilation, and hemorrhage. Abdominal tenderness and guarding is common, and bowel sounds are often decreased or absent. Pleural effusions are most often found on the left, but may be bilateral. Mild jaundice is not unusual, but bilirubin levels greater than 4 mg/dL suggest extrahepatic obstruction or underlying liver disease. Dark discoloration in the back, flank, or the paraumbilical region may arise from any retroperitoneal hemorrhage, including hemorrhage from pancreatitis.

Laboratory tests

Although the gold standard for diagnosing acute pancreatitis is a direct histological examination of the pancreas, this is rarely available. The goals of diagnostic tests for pancreatitis are to noninvasively establish the diagnosis and cause in patients with abdominal pain and to determine the prognosis. Clinicians should be mindful that a number of factors influence the level of serum markers of pancreatitis. First, serum levels of pancreatic enzymes are the sum of tissue production, release into the blood, and clearance. Thus, in patients with renal failure, the serum amylase may increase because the kidney does not clear the enzyme. Second, the measured enzyme activities may be influenced by a number of "serum factors" and may not reflect absolute enzyme levels. For example, hyperlipidemia is known to reduce routine serum amylase determinations to give an erroneous reading. Third, enzymes may be produced from nonpancreatic tissues, and this may limit the specificity of serum enzyme assays. In general, the higher the enzyme levels the better the chance that one is dealing with pancreatitis. Finally, standard enzyme assays, such as the amylase and lipase assays, provide no information on the severity of the pancreatitis.

Amylase

The serum amylase level has been the biochemical standard for diagnosing acute pancreatitis. Many organs generate amylase, an activity that hydrolyzes the internal 1–4α-linkages of starch. Because there are no circulating inhibitors of amylase activity, measurements of amylase activity in serum are reliable. Lactescent sera may inhibit amylase, but this effect can be eliminated by sample dilution. Although many tissues synthesize amylase, most of the serum activity originates from the pancreas (~ 40%) and the salivary glands (~ 60%). P-isoamylase arises from the pancreas and S-isoamylase from the salivary glands as well as other tissues such as the fallopian tubes and lung. Pancreatic amylase enters the blood through an unknown pathway and has a serum half-life of about 2 h. Although the major portion of serum amylase and other pancreatic enzymes is probably cleared by the reticuloendothelial system, about one-fourth of serum amylase is excreted in its intact form by the kidney.

Increased serum amylase during acute pancreatitis results from both enhanced release into the blood and decreased renal clearance. Serum amylase levels increase within the first hours after the onset of pancreatitis and parallel serum lipase levels. After an attack, however, the serum amylase falls much more rapidly than lipase, and may return to normal within 24 h. Lipase levels are more reliable indicators of pancreatitis in patients who are first seen several days after the onset of their illness (Fig. 68.14). In most situations, the degree of amylase elevation does not identify the cause or severity of pancreatitis. Elevations of serum amylase levels tend to be less in patients with alcoholic pancreatitis, pancreatic cancer, or penetrating ulcers, compared with patients with gallstone disease.

Defining abnormal values influences the sensitivity and specificity of the total serum amylase. Cutoff values of just above the normal range have been estimated to yield sensitivities greater than 90%, but specificities of less than 70% for acute pancreatitis. If the cutoff value is increased to three times the upper limit of normal, the specificity is near 100%, but the sensitivity may fall below 60%. Nonspecific increases of one- to two-fold in the serum amylase have been reported after cigarette smoking [215].

In an attempt to enhance the specificity of amylase measurements, amylase isoforms may be measured. P-isoamylase

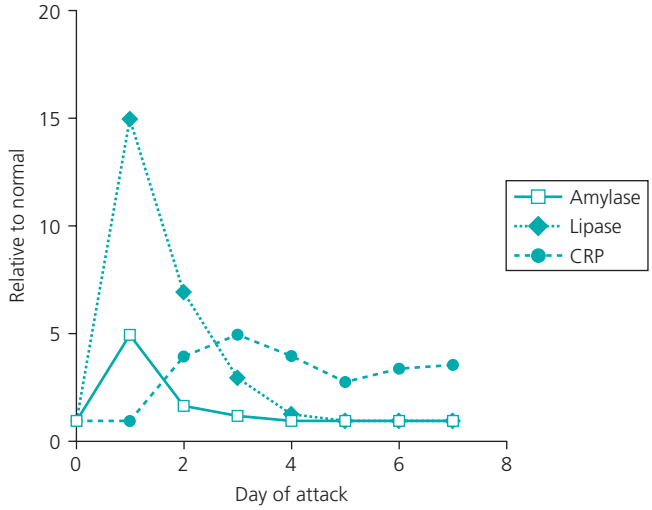

Figure 68.14 Serum markers of pancreatic injury.

is probably best used to confirm that an elevated total amylase level arises from the pancreas [216]. The clinical value of measuring P-isoamylase may be compromised by the inability of the assay accurately to measure small amounts of this isoform. Furthermore, P-isoamylase levels may increase in the absence of pancreatitis in patients with biliary tract disease, intestinal perforation, intestinal obstruction or ischemia, and ruptured abdominal aortic aneurysms.

Diseases of the salivary glands may lead to an elevated level of S-isoamylase; however, S-isoamylase levels may increase in the absence of salivary disease in chronic alcoholics, postoperative states, lactic acidosis, patients with anorexia nervosa and bulimia, after esophageal perforation, and in neoplasms such as pulmonary, gastric, and breast carcinoma, and myeloma.

Macroamylasemia

On occasion, a persistently elevated serum amylase is encountered in the absence of symptoms referable to the pancreas. An uncommon condition that can lead to such an elevated serum amylase is macroamylasemia. Amylase is normally found in the bloodstream as a molecule with a molecular weight of 45 kDa, but macroamylase often has a molecular weight of greater than 200 kDa. The normal ratio of pancreatic to salivary amylase is maintained in macroamylasemia. The high-molecular-weight macroamylase may result from antibodies complexed to amylase or from amylase polymers [217]. Unlike normal amylase, the macroamylase complex cannot enter the renal tubule for excretion and accumulates in the serum. Several methods can be used to diagnose macroamylasemia. First, amylase-to-creatinine clearance ratios of less than 1% strongly support the diagnosis. To confirm the diagnosis in patients with a low clearance, the clinical laboratory may determine the molecular weight of the serum amylase. Alternatively, immunological assays also may be used. Acquired macroamylasemia may occasionally signal the presence of a lymphoproliferative disorder.

Lipase

Rapid and reproducible methods for measuring serum lipase are available. Lipase activity is generated by a number of gastrointestinal tissues, including the pancreas, intestine, and liver and biliary tract, and from lingual and gastric sources. In some laboratory assays, the serum lipoprotein lipase activity is also detected [218]. The contribution of these various sources of lipase to serum lipase activity is not clear. Furthermore, the different substrates used in the various commercial assays may affect the specificity of the lipase measurement for pancreatic lipase. The least specific seems to be the Ektachem test, which has been found to have a specificity as low as 25% [219]. For many clinicians, the serum lipase has supplanted the amylase as the single test of choice for the diagnosis of pancreatitis. In most series, it is as sensitive and more specific than the total serum amylase, and promises to improve further when the L2 pancreatic lipase is measured. This enhanced specificity of the lipase level compared with the amylase level also has been reported in alcoholics [220]. Because lipase levels increase in parallel with serum amylase levels, lipase is a useful early marker of pancreatitis. The lipase level remains elevated longer than the amylase level, and thus may help to diagnose pancreatitis after an acute attack has passed (Fig. 68.14). Another advantage of lipase is that levels are normal in diabetic ketoacidosis and macroamylasemia.

Other pancreatic enzymes

Presumably all pancreatic enzymes are released into the blood during acute pancreatitis. Serum trypsin, chymotrypsin, elastase, ribonuclease, and phospholipase A2 have all been reported to be elevated in acute pancreatitis, but the specificity of these tests has not been sufficiently defined.

Urinary enzyme levels

Measurements of urinary enzyme levels have been used to diagnose acute pancreatitis. These include urinary trypsinogen 2 [221] and urinary levels of activation peptide of carboxypeptidase B. Both use a simple, rapid dipstick assay, and the former has reported sensitivities of 65%–95% and specificities above 90% for diagnosis of acute pancreatitis [222,223]. These findings require further confirmation. Urinary amylase levels, at one time advocated for improved sensitivity of diagnosis of acute pancreatitis, reflect the patient's intravascular volume status and renal function and probably do not improve the accuracy of diagnosis compared with serum enzyme levels.

Trypsinogen activation peptide

Premature activation of trypsinogen within the pancreas is thought to be an early step in pancreatitis. The small peptide removed during activation of trypsinogen to trypsin is known as trypsinogen activation peptide (TAP). Levels of TAP in the blood or urine reflect trypsinogen conversion to trypsin. Although no more accurate than serum amylase for diagnosis of acute pancreatitis, determinations of serum and urine levels of TAP have been reported to separate severe from mild pancreatitis when measured within the first 36 h of disease [224].

Inflammatory markers

The inflammatory response is a prominent component of pancreatitis and increases in parallel with its severity. Leukocytosis is common, and severe pancreatitis has been associated with leukemoid reactions even in the absence of infection. Several serum markers have been used to quantitate the inflammatory response. Neutrophil-specific elastase is released by inflammatory cells, and elevated serum levels are detected within the first 12–24 h of pancreatitis. Interleukin-6, released by macrophages, also increases during the acute phases of pancreatitis. Acute-phase react-

ants such as C-reactive protein (CRP) are induced by IL-6 and increase by the second day after the onset of acute pancreatitis [41]. Inflammatory markers may increase during any inflammatory process, and are not specific for diagnosis of pancreatitis. In contrast to amylase and lipase measurements, however, some of these markers have prognostic value as discussed below.

Markers of biliary tract involvement

Differentiation between biliary and nonbiliary forms of pancreatitis has important implications for treatment. Both biochemical and radiological tests are useful, but in some patients identification of a biliary cause may require EUS, bile microscopy, or empirical cholecystectomy. The timing of laboratory tests and ultrasound also affects their interpretation, especially when biliary tract obstruction is early in its course or when it is intermittent.

Most patients with gallstone pancreatitis have elevations of the serum liver tests, and the alanine aminotransferase (ALT) is the single most sensitive liver test for acute biliary obstruction by a stone. A rapid rise and fall in the serum liver tests is characteristically seen in gallstone pancreatitis in association with transient biliary obstruction at the papilla. Fluctuation is especially helpful in patients with chronic liver disease who have stable baseline elevations in aspartate aminotransferase (AST) and ALT levels. In addition, marked elevations of the amylase concentration of greater than 2000 IU/L also favor a biliary source [225]. The ratio of lipase to amylase may be greater in alcoholic than in biliary pancreatitis.

Noninvasive indicators of persistent bile-duct stones are useful in the workup of patients with gallstone pancreatitis. Laboratory scoring systems, such as the Ranson or modified Glasgow criteria, can identify patients whose biliary pancreatitis is predicted to be severe; these patients, in turn, are more likely to harbor persistent ductal or ampullary stones. Hyperbilirubinemia is associated with a higher incidence of retained bile-duct stones in gallstone pancreatitis [226,227]. Early trends in the serum liver tests and pancreatic enzyme levels are useful. Patients in whom all these values decrease over the first 48 h of hospitalization have a low (8%) risk of a persistent stone, whereas those in whom any of these lab values increase have a moderate (30%) risk of a persistent bile-duct stone [228]. None of these predictors is accurate enough to replace direct bile-duct imaging, but may be useful in selecting patients for EUS, magnetic resonance cholangiopancreatography (MRCP), or ERCP rather than elective intraoperative cholangiography.

Imaging

Abdominal radiographs

To exclude nonpancreatic diseases such as intestinal perforation, standard and upright chest and abdominal radiographs are recommended in evaluation of severe abdominal pain. Plain radiographs may be omitted if CT is available immediately.

A variety of radiographic findings have been associated with pancreatitis. Pleural effusions are most common on the left, but may be bilateral and rarely are limited to the right pleural space [229]. Intestinal gas patterns may demonstrate an ileus pattern or an isolated dilated loop of small bowel overlying the pancreas known as the sentinel loop. Colonic obstruction may result in air in the right and transverse colon that abruptly terminates at the splenic flexure, the so-called "colon cutoff sign." Loss of the psoas margins and increased separation between the stomach and colon suggest pancreatic inflammation. Pancreatic calcification or calcified gallstones may suggest an alcoholic or biliary etiology, respectively.

Sonography

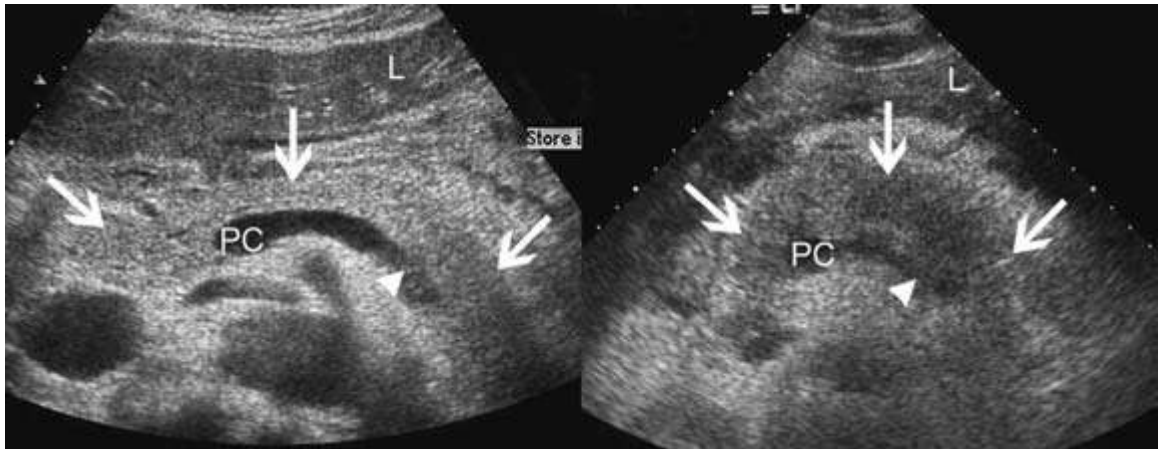
When the pancreas is inflamed it appears hypoechoic on sonography, because of increased water in the parenchyma (Fig. 68.15). Ultrasound is thus a relatively sensitive test for the diagnosis of acute pancreatitis, when the pancreas is seen. Although ultrasonography can be performed rapidly and at the patient's beside, pancreatic visualization is limited by intestinal gas or adipose tissue in 30%–40% of patients. This is especially common in patients with ileus due to their pancreatitis. Ultrasonography may miss focal masses or fluid collections, especially in and around the pancreatic tail. Its greatest value is in evaluating the biliary tract for gallstones, sludge, or ductal dilation [145,146]. Ultrasound is the single best noninvasive test for the detection of gallbladder stones, with a sensitivity of about 95%. It is much less reliable for direct visualization of a bile-duct stone, because the common bile duct is often obscured by overlying bowel gas.

Computed tomography

Computed tomography is a valuable tool for pancreatic imaging. In contrast to ultrasound, which demonstrates changing echogenicity in the parenchyma of the gland, the CT diagnosis of pancreatic inflammation is made based on pancreatic enlargement, effacement of the usual lobulated contour of the pancreas, inhomogeneity of the pancreatic parenchyma, or fluid infiltrating the peripancreatic fat (Fig. 68.16). Although CT and ultrasound are equally sensitive for diagnosis of pancreatitis, CT is better than ultrasound for detection of focal pancreatic masses or fluid collections because it reliably visualizes the entire gland.

Dynamic CT performed during bolus administration of intravenous contrast can demonstrate areas of poor perfusion or nonperfusion in the pancreas [19]. This finding is typically interpreted as necrosis of the poorly perfused segment; estimates of pancreatic necrosis by dynamic CT correlate with observations made at surgery. The CT finding of necrosis identifies patients who are at higher risk for pancreatic infection and death.

Investigators have debated whether early administration of bolus intravenous contrast worsens pancreatitis. Studies in rats have shown decreased pancreatic capillary flow rates



(a) (b)

and decreased pancreatic oxygen saturation after intravenous contrast administration [230]. These effects persisted at 60 min after contrast was given. There is no compelling evidence of this phenomenon in humans, however. A retrospective study at a university hospital found that patients who underwent contrast-enhanced CT had longer hospitalizations than those who did not, despite similar Acute Physiology and Chronic Health Evaluation (APACHE) II scores on admission [231]. A subsequent prospective study randomized patients with severe pancreatitis to CT on the first hospital day with or without bolus intravenous contrast. There was no difference in systemic markers of inflammation, length of hospital stay, or mortality [232]. In practice, a contrast-enhanced CT is usually unnecessary in the first 24 h of hospitalization, but early CT may be performed if it will have an important effect on early management of the individual patient.

Helical CT technique has improved CT sensitivity for detection of bile-duct stones to 85% [233]. Detection of ductal stones using CT is still limited by stone composition; calcium must be present in sufficient amounts to yield a CT density different than that of the surrounding bile or soft tissue. When looking for biliary stones, helical CT should be done without contrast so that a bright rim at the periphery of a stone is not mistaken for contrast enhancement of the bile-duct wall.

Magnetic resonance imaging

Magnetic resonance imaging (MRI) is similar to CT when imaging the acutely inflamed pancreas (Fig. 68.17) [234]. When intravenous gadolinium is given, MRI demonstrates areas of poor pancreatic perfusion similar to those identified with CT. Animal studies have shown no deleterious effect of intravenous gadolinium on the inflamed pancreas. Although MRI is more cumbersome and expensive than CT and more difficult to perform quickly, it does have fewer contraindications (such as pregnancy and contrast allergy), and can detect pancreatic duct disruption. Like EUS, MRI is more accurate than CT for demonstration of solid debris in a pancreatic fluid collection; complex collections often have a homogeneous appearance on CT [235]. However, MRI does not demonstrate pancreatic calcifications.

Secretin-stimulated MRI has a role in the diagnosis of functional pancreatic duct outlet obstruction, and in noninvasive diagnosis of pancreatic duct disruption and leak [236]. Magnetic resonance angiography (MRA) and MRCP are additional techniques that offer noninvasive diagnosis of vascular complications and persistent bile-duct stones in acute pancreatitis. The sensitivity of MRCP exceeds 90% for bile-duct stones, although its yield in patients with normal-caliber ducts and small ampullary stones is not as well defined.

Endoscopic retrograde cholangiopancreatography (ERCP)

There is no role for ERCP in establishing the diagnosis of acute pancreatitis. Most patients with acute pancreatitis have normal pancreatograms, although some may have pancreatic duct strictures or ductal disruptions. However, ERCP is useful in the differential diagnosis of otherwise unexplained, recurrent pancreatitis, especially for diagnosis of mild chronic pancreatitis, pancreas divisum, or sphincter of Oddi disease. It has been used to diagnose and treat persistent bile-duct stones in acute pancreatitis, as discussed in section "Urgent ERCP and EUS in gallstone pancreatitis".

Endosonography

Endoscopic ultrasound (EUS) is useful in some patients with acute pancreatitis. It is a sensitive test for detection of persistent bile-duct or ampullary stones and can be used to identify

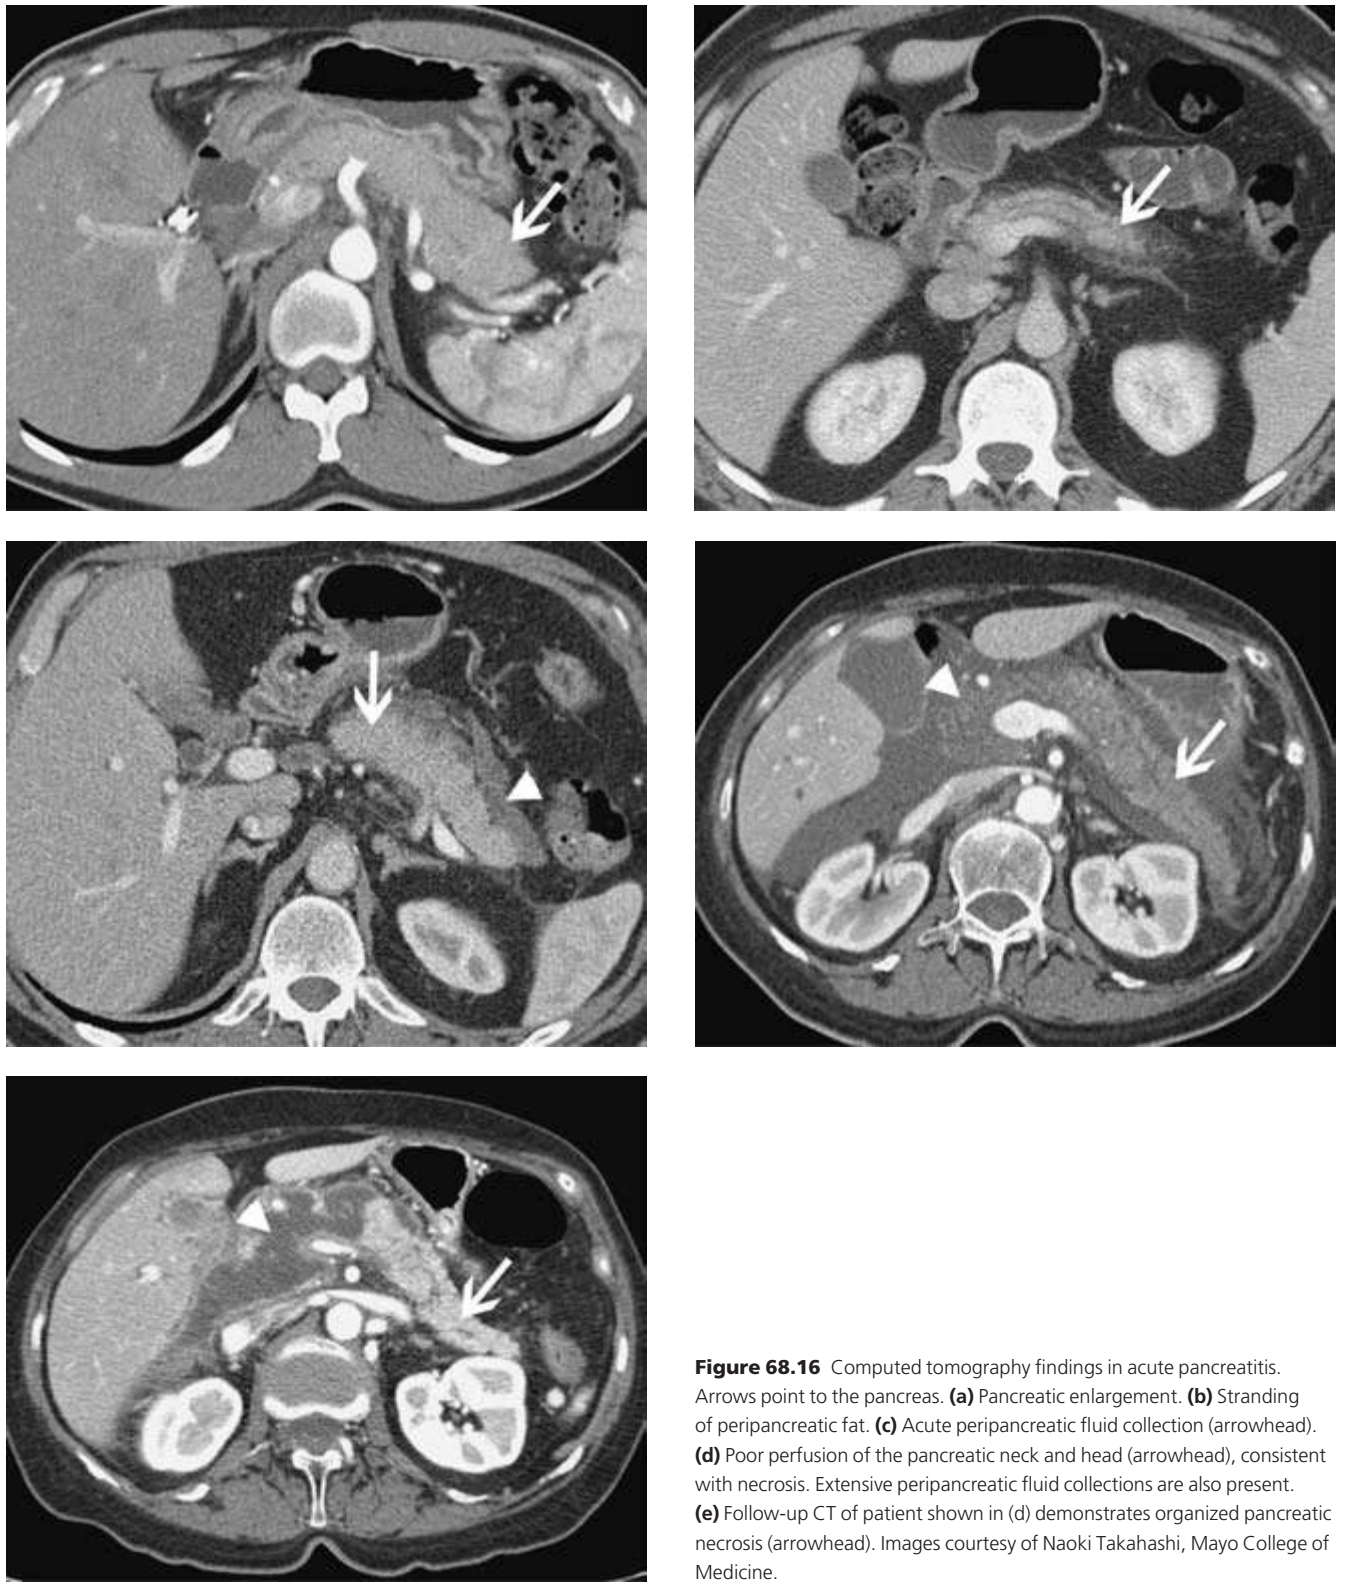

Figure 68.16 Computed tomography findings in acute pancreatitis. Arrows point to the pancreas. **(a)** Pancreatic enlargement. **(b)** Stranding of peripancreatic fat. **(c)** Acute peripancreatic fluid collection (arrowhead). **(d)** Poor perfusion of the pancreatic neck and head (arrowhead), consistent with necrosis. patients likely to benefit from ERCP [237]. Endosonography is also useful for the differential diagnosis of unexplained acute pancreatitis, because it demonstrates biliary sludge and stones missed with other imaging modalities, as well as small pancreatic or ampullary tumors, pancreas divisum, and chronic pancreatitis [214]. Complex material within a pancreatic fluid collection can be demonstrated by EUS, and it can guide endoscopic pseudocyst drainage.

Use of cross-sectional imaging studies in acute pancreatitis

The choice of imaging modality for patients with acute pancreatitis depends on the clinical question that needs to be answered. Imaging studies can establish the diagnosis of pancreatitis, aid in differential diagnosis, provide prognostic information, or assess possible complications.

When the diagnosis of pancreatitis is uncertain both ultrasound and CT may be useful. A patient with rapidly resolving biliary pancreatitis may have near normal serum enzymes but persistent pancreatic edema seen on ultrasound, or peripancreatic inflammatory changes on CT. Computed tomography can show changes of chronic pancreatitis or focal pancreatic masses.

For differential diagnosis, the choice of imaging test depends on the diagnosis suspected. When biliary pancreatitis seems likely, ultrasound is the standard investigation because it detects almost all gallbladder stones. When chronic pancreatitis or an underlying pancreatic malignancy is suspected, CT is more useful. Endoscopic ultrasound may also be warranted to pursue these diagnostic possibilities in the face of negative noninvasive imaging studies. When a metabolic or drug-induced pancreatitis is likely, imaging tests may still be indicated to exclude other common causes such as stones.

In patients with biliary pancreatitis, imaging studies such as EUS or MRCP may usefully identify patients with persistent bile-duct or ampullary stones. Early bile-duct imaging is particularly appropriate when the pancreatitis is severe or laboratory trends suggest an increased risk of a persistent stone.

Contrast-enhanced CT or MRI can identify patients with necrosis, and these patients may benefit from prophylactic antibiotics. However, CT is not necessary in every patient with pancreatitis. Necrosis is uncommon in patients with clinically mild disease who improve rapidly in the hospital. Serial hematocrits and the concentration of C-reactive protein on the second hospital day are useful predictors of the presence or absence of necrosis, as described in the section on complications. When necrosis is suspected or the patient is not improving over the first 48 h of hospitalization, contrast-enhanced CT or MRI is usually worthwhile.

Computed tomography is also valuable in the diagnosis and management of local complications of acute pancreatitis. Jaundice or a marked drop in hematocrit may also be indications for CT. When thrombosis of the splenic or superior mesenteric veins is suspected, MRA or CT may be useful.

Evaluation of severity

Severe pancreatitis is defined as the occurrence of a local or systemic complication of the disease, or death. Definitions of both local and systemic complications of pancreatitis were described at the 1992 Atlanta consensus conference; subsequently multiple organ dysfunction syndrome (MODS) was defined in a broad range of patients with critical illness, and MODS definitions of organ dysfunction have also been used to define severe acute pancreatitis (Table 68.3). There are

Table 68.3 Complications of acute pancreatitis, as defined by the Atlanta consensus conference and the multiple organ dysfunction syndrome (MODS) score

	Atlanta definition[a]	MODS score ≥ 2[b]
Local complications		
Acute fluid collections	Occur early, lack a wall	
Necrosis	Areas of nonviable parenchyma	
Acute pseudocysts	Collection of pancreatic juice Enclosed by a wall	
Pancreatic abscess	Circumscribed collection of pus	
Organ dysfunction		
Shock	Systolic blood pressure < 90 mmHg	Pressure-adjusted heart rate (PAR)[c] > 15
Pulmonary	P_aO_2 ≤ 60 mmHg (room air)	PO_2/F_iO_2 ≤ 225
Renal	Creatinine > 2 mg/dL after rehydration	Creatinine > 2.26 mg/dL
GI	> 500 mL GI blood loss in 24 h	
Hematological	Platelets < 100 000/mm^3; fibrinogen < 1 g/L; fibrin split products > 80 μg/mL	Platelets ≤ 80 000/mm^3
Metabolic	Serum calcium < 7.5 mg/dL	
Neurological		Glasgow Coma Score ≤ 12

a Bradley et al. [9].
b Marshall et al., with hepatic dysfunction excluded as explained in the text [249,272].
c PAR = product of the heart rate multiplied by the ratio of the right atrial (central venous) pressure to the mean arterial pressure.

several important reasons to identify the severity of acute pancreatitis. Because severity correlates with prognosis, such evaluation may allow the clinician to predict the patient's course and anticipate complications or the need for closer monitoring in an intensive care unit. Prognostic information may guide the use of prophylactic antibiotics, urgent bile-duct imaging, and early ERCP. Finally, prognostic markers allow the clinical investigator to measure the success or failure of therapeutic interventions. The tools used to predict severity and prognosis fall into three categories: specific laboratory tests, clinical and physiological assessment, and CT.

Laboratory tests

The standard laboratory tests used to diagnose pancreatitis provide little prognostic information, but other tests appear to separate patients with mild disease from those with severe disease. The first group of tests measures the severity of the inflammatory response. These include the neutrophil elastase and the monokine IL-6 tests. Both are elevated within 24 h and correlate with the severity of pancreatitis. C-reactive protein is induced by IL-6 and is a later marker of severity, distinguishing patients with severe disease when measured at 48 h (Fig. 68.18). Because C-reactive protein is easily and inexpensively measured and appears to be a good prognostic marker, it should be widely used to assess prognosis.

The hematocrit is a simple, readily available laboratory test that provides prognostic information in acute pancreatitis [238]. An elevated hematocrit (> 44%) at the time of hospital admission, or failure of the hematocrit to decrease in the first 24 h of hospitalization, are seen in almost all patients who develop pancreatic necrosis or distant organ failure [238]. Perhaps the most useful benefit of the hematocrit is its ability to exclude severe disease; a normal hematocrit on admission has a negative predictive value for severe pancreatitis of over 95% [239], and may be used to identify patients who do not require CT.

The finding that a rising hematocrit is associated with necrosis in up to 50% of cases has raised the possibility that aggressive fluid resuscitation could prevent pancreatic necrosis. Failure of the hematocrit to normalize has not been linked with disease severity in all studies, however [240], and limited available treatment data do not prove the hypothesis that aggressive hydration prevents necrosis [241].

The TAP (trypsinogen activation peptide) assay is an indirect measure of the amount of active trypsin. From a pathophysiological standpoint, this is an elegant measure of severity: the more trypsin activation, the more pancreatic damage. In one large prospective study, TAP levels discriminated between mild and severe disease [224]. In another prospective study, urinary TAP levels were more accurate than initial hematocrit for prediction of disease severity [242]. Unfortunately, TAP assays are not yet widely available.

Laboratory tests may usefully predict the likelihood of pancreatic necrosis, which is in turn linked to severe disease. A serum C-reactive protein level greater than 150 mg/L is seen in 95% of patients with necrosis by the second hospital day

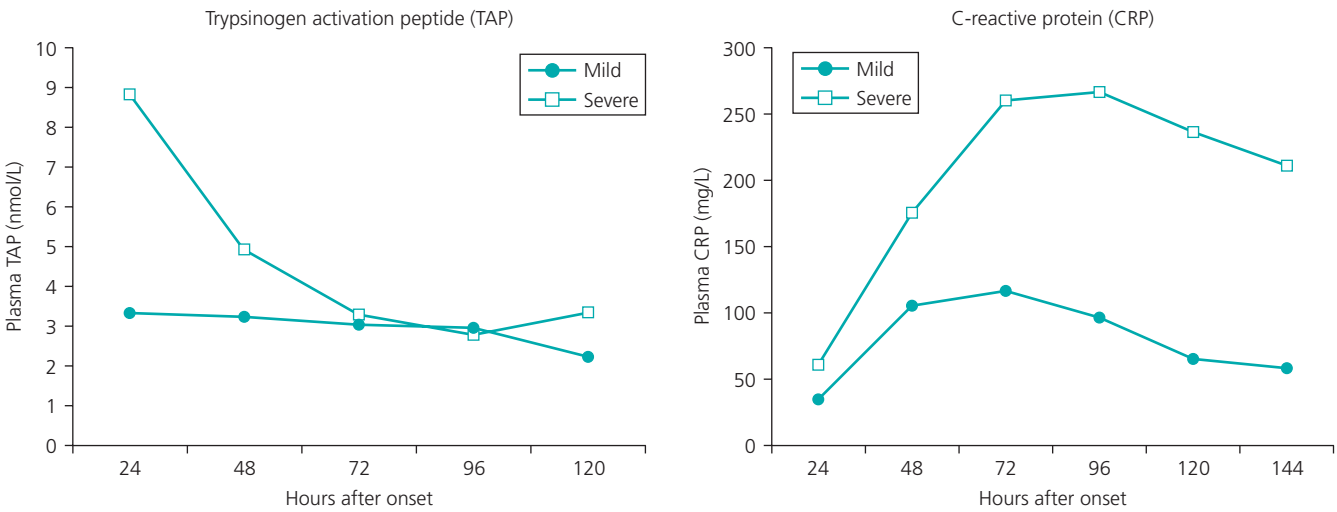

Figure 68.18 Serum markers of severity. Serum values of the trypsinogen activation peptide (TAP) and C-reactive protein (CRP) as a function of the duration and severity of acute pancreatitis. Derived from Kemppainen et al. [224], and Wilson C, Heads A, Shenkin A, Imrie CW. C-reactive protein, antiproteases and complement factors as objective markers of severity in acute pancreatitis. Br J Surg 1989;76:177.

(Fig. 68.18) [243]. When the hematocrit is less than 44% on admission and does not increase in the first 24 h, necrosis has been demonstrated in only 4% [238].

Computed tomography

Both non-contrast CT and contrast-enhanced CT yield useful prognostic information. A prognostic scoring system called the CT Severity Index (Table 68.4) has been shown to correlate with the Ranson criteria for assessing severity [19]. In one study, patients with CT Severity Index scores up to 2 had only 4% morbidity and no mortality, but those with scores from 7 to 10 experienced 92% morbidity and 17% mortality (Fig. 68.19). Contrast-enhanced CT demonstrates the presence and extent of pancreatic necrosis, and is hence an important predictor of complications and death, as discussed in the section on pancreatic necrosis.

Table 68.4 Computed Tomography Severity Index

	Points
Grade of acute pancreatitis	
A: Normal pancreas	0
B: Pancreatic enlargement	1
C: Inflammation confined to pancreas and peripancreatic fat	2
D: One peripancreatic fluid collection	3
E: Two or more fluid collections	4
Degree of necrosis	
No necrosis	0
Necrosis of one-third of pancreas	2
Necrosis of one-half of pancreas	4
Necrosis of more than one-half	6

Computed Tomography Severity Index = grade points + degree of necrosis.

Clinical and physiological assessment

The criteria established by Ranson and colleagues are still the most widely applied to the assessment of acute pancreatitis. The Ranson criteria (Table 68.5) distinguish between mild and severe pancreatitis about 80% of the time. As shown in Fig. 68.19, Ranson score correlates with morbidity and mortality [244]. The disadvantage of the Ranson criteria is that they include 11 values that must be monitored over 48 h. Blamey and colleagues developed the Glasgow classification, which can be calculated any time within the first 48 h of hospitalization and measures only eight parameters (Table 68.5) [245]. The simplified Glasgow criteria appear to have prognostic accuracy similar to that of the Ranson criteria. The Glasgow criteria were developed in a population of predominantly biliary pancreatitis, whereas the Ranson criteria were developed in patients with more alcoholic pancreatitis.

Although some prognostic classifications have dropped the base deficit and fluid requirements from the Ranson criteria, others have identified obesity as an independent risk factor. The higher risk in the obese patient may result from respiratory compromise from physical restraints, or from the provision of toxic substrates such as free fatty acids from triglycerides and harmful cytokines from peritoneal fat stores.

The Acute Physiology and Chronic Health Evaluation (APACHE) II has been used to establish the prognosis in patients with pancreatitis [246]. This system uses 14 routinely measured parameters of physiological activity and biochemical function, and generates a numerical score that

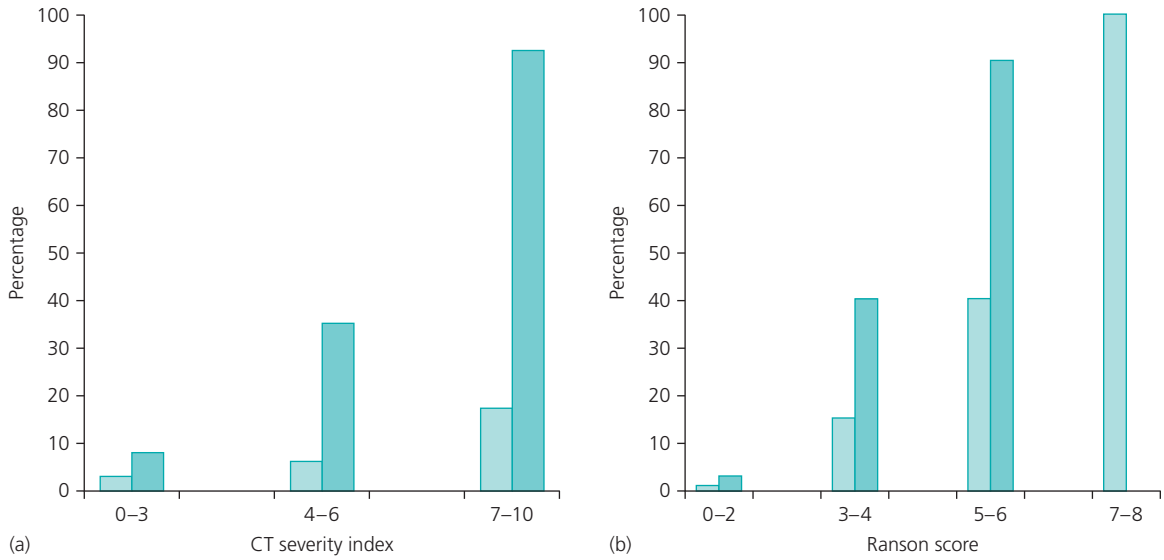

Figure 68.19 Stratification of severity according to Computed Tomography (CT) Severity Index (Table 68.4) and Ranson criteria (Table 68.5). The light bar represents mortality. Morbidity (dark bar) was defined as greater than 7 days in the intensive care unit. Derived from Balthazar et al. [19] and Ranson [244].

Table 68.5 Ranson criteria and simplified Glasgow prognostic scoring criteria

Ranson criteria	Simplified Glasgow criteria
On admission	**Within 48 h**
Age > 55 years	Age > 55 years
WBC > 16 000/mm^3	WBC > 15 000/mm^3
LDH > 350 IU/L	LDH > 600 IU/L
Glucose > 200 mg/dL	Glucose > 180 mg/dL
AST > 250 IU/L	Albumin < 3.2 g/dL
	Calcium < 8 mg/dL
Within 48 h	Arterial Po_2 < 60 mmHg
Hematocrit decrease by > 10%	Urea > 45 mg/dL
Urea nitrogen increase by > 5 mg/dL	
Serum calcium < 8 mg/dL	
Arterial Po_2 < 60 mmHg	
Base deficit > 4 mEq/L	
Estimated fluid sequestration > 6 L	

AST, aspartate aminotransferase; LDH, lactate dehydrogenase; WBC, white blood cells.

depends on the deviation of those parameters from the normal range. The patient's age, organ insufficiency, neurological state, and postoperative state are also weighted. The potential advantage of the APACHE is that it can be calculated instantaneously from routine measurements. The initial value discriminates patients at high risk for complications and death, and trends in the patient's APACHE score over time add to its predictive value. A major shortcoming of this classification is its complexity. It is difficult to apply the APACHE system routinely outside of an intensive care unit.

The presence of the systemic inflammatory response syndrome (SIRS) is an important early predictor of multiple organ dysfunction syndrome (MODS) and mortality from acute pancreatitis, particularly if SIRS persists beyond 48 h. The systemic inflammatory response syndrome is defined by simple clinical data (Table 68.6) [247,248] that are readily available for patients with acute pancreatitis. In one large series, the prevalence of SIRS among patients with acute pancreatitis was 21% on hospital admission, and 18% had persistent SIRS at 48 h. Persistent SIRS was associated with development of MODS. The mortality rate was 0.7% in patients without SIRS, 8% in patients with transient SIRS, and 25% in those with persistent SIRS beyond 48 h [249].

Are these prognostic scoring systems of use to the clinician? A group of experienced pancreatic surgeons compared bedside assessment at admission and after 48 h with the APACHE II, Ranson, and Glasgow scores for predicting the severity of acute pancreatitis [246]. Bedside assessment alone missed over half of the cases that ultimately proved to have a complicated course. Thus, a high score on a standardized scoring system alerts the clinician to the possibility of complications. This in turn should prompt frequent reevaluation of the patient and the adequacy of supportive treatment, perhaps in an intensive care unit.

Table 68.6 Systemic inflammatory response syndrome (SIRS)[a]

Temperature > 38°C or < 36°C
Heart rate > 90 beats/min
Respiratory rate > 20 breaths/min or arterial Pco_2 < 32 mmHg
WBC count > 12 000 or < 4000 cells/mm^3

a SIRS is present if two or more of the four criteria are present [249].

Local complications

Local complications of pancreatitis include fluid collections, retroperitoneal hemorrhage, vascular and splenic complications, and duodenal, biliary, or colonic obstruction. The commonest of these is the development of a pancreatic or peripancreatic collection. A useful classification of pancreatic collections was adopted at a consensus conference on acute pancreatitis held in Atlanta in 1992, and this has since been widely accepted, replacing older terminology such as "phlegmon" [9]. The Atlanta classification distinguishes acute fluid collections, necrosis, pseudocysts, and abscesses. Each of these entities has a different pathology, natural history, and treatment.

Pancreatic fluid collections

Acute fluid collections

Acute fluid collections form in or near the pancreas, and are common among patients with pancreatitis. They occur early in the course of the acute illness, and do not have a defined wall. Fluid collections may be simple and exhibit a uniform CT density that approximates that of water; or they may be complex with multiple CT densities and poorly defined margins (Fig. 68.16). Even those that appear simple on CT often contain locules and inflammatory debris when imaged by MRI or EUS.

Most acute fluid collections resolve spontaneously. The factors determining resolution of an acute collection, versus persistence of the collection and progression to a pseudocyst, are incompletely understood. An underlying pancreatic duct disruption that empties into a fluid collection certainly contributes to their persistence and enlargement in some patients. Nevertheless, prospective studies show that ductal disruptions often resolve with conservative management alone, without surgical or endoscopic intervention [250].

Although some have advocated drainage of acute fluid collections, evidence demonstrating a benefit for such intervention is lacking. Acute collections may be difficult to drain percutaneously, and CT scans often underestimate the complexity of these collections. Unless an acute collection is rapidly expanding or associated with clinical evidence of infection, it should be observed. Infection is an uncommon complication; if suspected, diagnosis is best made by sterile aspiration of the fluid collection under CT guidance, with Gram stain and culture of the aspirate. Infected collections have to be drained and have been successfully treated using percutaneous catheters. A percutaneous catheter should not be placed unless infection is confirmed, as it can serve as a portal for entry of bacteria into a previously sterile collection. Because fluid collections are frequently associated with acute pancreatitis, and most resolve spontaneously, a fluid collection should be defined as a pseudocyst only if it persists for more than 4 weeks.

Necrosis and infected necrosis

Any form of acute pancreatitis may progress to severe disease and extensive pancreatic necrosis. Pancreatic necrosis may result from ischemia or marked inflammation and represents a severe form of disease. Necrosis may affect the pancreas diffusely or focally, and necrotic areas may be separated by segments of viable tissue. Histological exam may show devitalized pancreatic tissue with vessel damage and necrosis of parenchyma and ducts, as well as hemorrhage and fat necrosis.

Pancreatic necrosis is diagnosed clinically with dynamic contrast-enhanced CT, which demonstrates well-marginated zones of nonenhanced pancreatic tissue (Fig. 68.16). Although some nonenhancing parenchyma may be viable, there is generally good correlation between CT, operative findings, and histology in patients with necrosis undergoing surgery. Computed tomography is less useful for diagnosis of peripancreatic fat necrosis.

Necrosis is uncommon in patients with clinically mild disease. Laboratory predictors of necrosis include a serum C-reactive protein level greater than 150 mg/L at 48 h (Fig. 68.18), a Ranson score greater than or equal to 3, or an APACHE II score exceeding 7. Necrosis is associated with other major complications and death from acute pancreatitis. Major complications of necrosis include distant organ failure and infected pancreatic necrosis. Early in the course of necrotizing pancreatitis there may be a marked systemic inflammatory response (SIRS) with increased capillary permeability, a sepsis-like syndrome, and other organ failure most often affecting the lungs. Organ failure is more likely in patients with necrosis of over 50% of the pancreas [251]. Infection of the necrotic pancreatic tissue may develop. Because there is no fibrotic wall or capsule to contain the infection, adjacent inflamed tissues become involved and overwhelming sepsis is likely unless adequate debridement of the infected tissue is achieved.

Infected pancreatic necrosis is a leading risk factor for death from acute pancreatitis. Infection of pancreatic necrosis occurs in 30%–70% of patients not receiving prophylactic antibiotics [252]. This high frequency is in large part due to increased bacterial translocation from the gut into the portal venous system, with seeding of the necrotic tissue. Alterations in mucosal villus architecture and bowel microvasculature occur in animal models of acute pancreatitis, with bacterial translocation from the intestine to the pancreas, liver, and spleen [253]. In patients, the same bacterial species that infect the pancreas can be previously cultured from the colon [254]. The prevention and treatment of infected necrosis is described in greater detail later (see "Antibiotic prophylaxis" below).

Infected necrosis may be heralded by a sudden increase in abdominal tenderness, high fever, marked leukocytosis, and bacteremia. The presentation may also be subtle, particularly in patients receiving prophylactic antibiotics, with persistent or worsening organ failure despite ongoing supportive

care. Negative blood cultures do not exclude the diagnosis. Although infection of pancreatic necrosis was thought to occur mainly after the first 10–14 days of illness, subsequent reports have stressed its occurrence earlier and later in the course of necrotizing pancreatitis.

The main diagnostic modality for infected necrosis is CT-guided fine-needle aspiration of the necrotic pancreatic tissue. Samples should be immediately examined by Gram stain, which has a high utility in this setting. Fungal stains are advisable as well, and cultures are also mandatory. Polymicrobial bacterial gram-negative enteric and anaerobic organisms are most common, but with the widespread use of prophylactic antibiotics bacterial gram-positive and fungal infections are increasingly frequent [255].

Laboratory predictors of infected pancreatic necrosis have been sought. The serum procalcitonin and IL-6 levels may distinguish between sterile and infected necrosis [256–258]. Further clinical experience with these markers of infected necrosis is desirable.

Sterile pancreatic necrosis has a variable clinical course. The necrotic tissue may gradually disappear, leaving residual inflammation and scar. In other cases the necrotic region gradually evolves into a region of organized pancreatic necrosis (Fig. 68.20). In a minority of patients, a persistent sequestrum of sterile pancreatic necrosis is responsible for persistent organ failure despite prolonged supportive care. Drainage of sterile necrosis may be considered in patients with persistent symptoms or organ failure, as described later (see "Drainage of sterile necrosis" below).

The term "organized pancreatic necrosis" has been used to describe a region of necrosis that is at least 4 weeks old and has developed a wall, but still contains necrotic material [259]. The distinction between organized pancreatic necrosis and pseudocyst has importance when nonsurgical drainage is considered. Organized pancreatic necrosis can be drained endoscopically using a transmural gastric or duodenal approach, or percutaneously. Aggressive endoscopic or percutaneous techniques are needed adequately to remove the

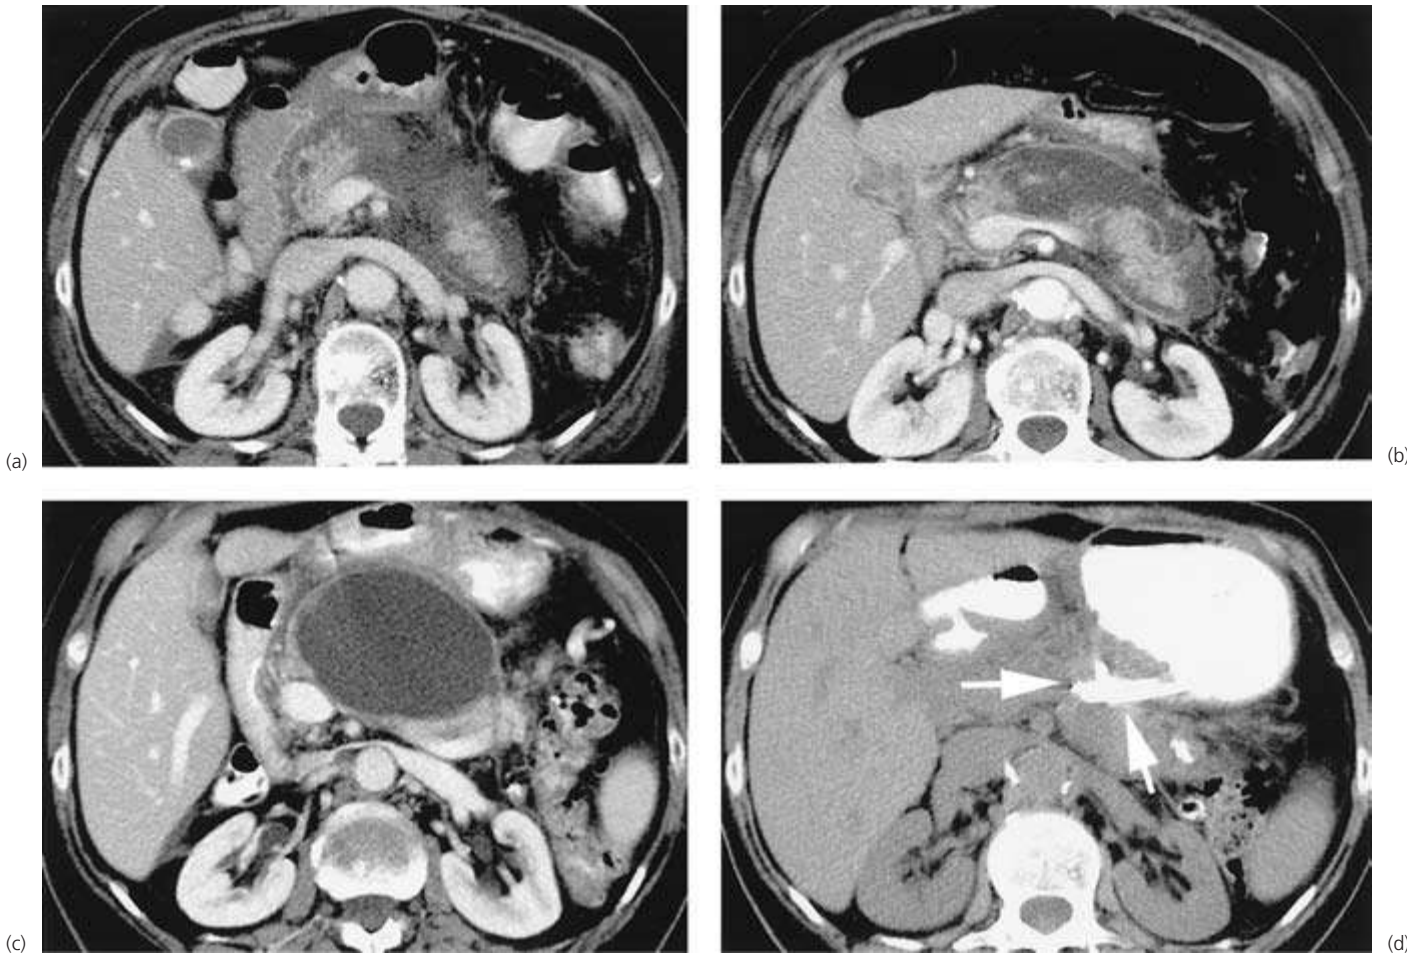

Figure 68.20 Evolution of central necrosis. **(a)** Necrosis of the pancreatic body in a patient with gallstone pancreatitis. **(b)** One week after onset of pancreatitis. **(c)** Seven weeks after onset. **(d)** The collection has resolved after endoscopic drainage with placement of multiple internal stents (arrows).

thick necrotic material, including creation of a large tract to the collection using large-caliber dilating balloons, placement of multiple stents and drains, lavage by percutaneous or nasocystic catheters, and direct endoscopy of the collection by the transmural or percutaneous tract for debridement of necrotic material. Attempts at drainage may otherwise result in a poorly drained, infected collection. The complexity of an organized area of pancreatic necrosis is often underestimated by CT, and both EUS and MRI have been used to identify solid material in these collections.

Necrosis is often accompanied by a disruption of the pancreatic duct. When the disruption occurs in the mid-portion of the pancreas, the necrotic region may gradually expand as pancreatic juice from the viable pancreatic tail drains into it. This so-called "disconnected duct syndrome" usually requires resection of the disconnected tail, sometimes with islet cell autotransplantation, although creation of a durable fistula to the gut has been described using endoscopic techniques.

Pseudocysts

Pseudocysts are collections of pancreatic fluid contained by a wall of fibrosis or granulation tissue. The presence of a well-defined wall distinguishes pseudocysts from acute fluid collections and pancreatic necrosis. An epithelial lining is absent (in contrast to true pancreatic cysts). Formation of a well-defined wall generally requires at least 4 weeks. Pseudocysts usually contain fluid rich in pancreatic enzymes, and often contain particulate matter.

The advent of pancreatic imaging by ultrasonography and CT led to the realization that pancreatic pseudocysts are common and appear in up to 10% of patients with acute pancreatitis [260]. Although they may form most frequently in patients with alcoholic pancreatitis, up to 30% of cases arise in gallstone pancreatitis. The most common presenting symptom of a pseudocyst is upper abdominal pain that is either constant or postprandial. Other symptoms referable to a pseudocyst include early satiety and nausea and vomiting secondary to gastric outlet obstruction. Pseudocysts may also enlarge rapidly, rupture, hemorrhage, leak pancreatic fluid, obstruct the biliary tract, compress the inferior vena cava, erode into surrounding structures, extend into the mediastinum, and become infected.

The risk of complications varies with the size of a pseudocyst and its age. Symptomatic pseudocysts may also be more prone to complications. Early reports based on ultrasound detection of pseudocysts in persistently symptomatic patients found a complication rate of 30%–50% in pseudocysts that persisted for more than 6 weeks, and were the basis for recommendations to drain all persistent pseudocysts. Subsequent studies of asymptomatic pseudocysts detected with liberal use of CT document a low incidence of complications, even in large pseudocysts, and show that most pseudocysts less than 6 cm in diameter resolved over time. One-third of lesions more than 10 cm in diameter also do well with observation alone [260].

Indications for early drainage include infection or progressive enlargement of the pseudocyst. Symptomatic pseudocysts typically require drainage. In the absence of symptoms, pseudocysts can be followed conservatively, although large lesions that fail to shrink with time should probably be drained. Pseudocysts can be drained endoscopically, percutaneously, or surgically. If there is a question about whether the lesion is a true pancreatic cyst or pancreatic cystic neoplasm rather than a pseudocyst, surgical drainage gives the opportunity to obtain a large piece of the cavity's wall for histological exam. This is especially important when a pancreatic "pseudocyst" is found in the absence of a clinical bout of pancreatitis, or in recent pancreatitis of unclear etiology (Fig. 68.21).

The location of a pseudocyst and its relationship to the pancreatic duct can affect the approach taken for cyst drainage. Pancreatography may be helpful in delineating obstruction of the pancreatic duct and ductal communication with a pseudocyst. Those that do not communicate are amenable to either internal or external drainage. Pseudocysts that communicate with the duct, especially when the duct is strictured or disrupted, often resolve slowly when drained externally, and percutaneous drainage may lead to a pancreaticocutaneous fistula. Such pseudocysts are best considered for internal drainage.

Endoscopic therapies are attractive nonsurgical options for pseudocyst drainage in many cases. Endoscopic techniques include transpapillary and transmural drainage into the stomach or duodenum with placement of internal stents. Pseudocysts of the pancreatic head may be best treated with transpapillary stenting, especially if the cyst communicates with the pancreatic duct and there is an associated ductal stricture. Transpapillary stenting is most successful when the stent traverses the ductal disruption [261,262]. A high incidence of major hemorrhage was initially reported with endoscopic transmural drainage of pseudocysts, but use of an over-the-wire Seldinger technique, rather than electrocautery, lowers the risk of major complications such as bleeding or perforation to less than 5% [263]. Endoscopic ultrasound can facilitate pseudocyst drainage, particularly when an obvious bulge is not visible endoscopically or venous collaterals are present [264]. Endoscopic drainage of infected pseudocysts has been described.

Percutaneous drainage is also a well-established method for draining sterile or infected pseudocysts. When technically possible, a transgastric approach is favored, as internal drainage into the stomach through a mature catheter tract can result. External drainage may otherwise result in persistent drainage of pancreatic juice through the external fistula created by the catheter.

Incomplete pseudocyst drainage by either endoscopic or percutaneous means may result in infection of the pseudo-

The patient developed epigastric pain without a discrete episode of pancreatitis. **(a)** Computed tomography demonstrates a round fluid collection of the pancreatic body with a well-defined wall. **(b)** Endoscopic retrograde cholangiopancreatography (ERCP) shows bowing of the pancreatic duct around the lesion, without communication. Pathology examination of the resected lesion showed cystadenocarcinoma.

cyst contents. This is particularly common in patients with "organized pancreatic necrosis" mistaken for a simple pseudocyst, as described above. A complex collection should be suspected in patients with necrosis that has evolved into a pseudocyst-like structure on serial CT scans. Prior to drainage, EUS or MRI may be used to assess for solid material in the cavity. If solid matter is present in the collection more aggressive endoscopic or percutaneous techniques are necessary for adequate treatment, such as placement of multiple stents and a nasocystic tube to allow lavage of the pseudocyst cavity.

There are several reasons why the fluid contents of a pseudocyst should be sampled during drainage. First, a high amylase concentration within a cyst probably reflects its persistent communication with the pancreatic duct and bodes a poor outcome for external drainage. Second, symptoms of pseudocyst infection may be indolent and suspected only after bacterial and fungal culture. Third, true cystic lesions of the pancreas, including cystic neoplasms, may be mistaken for pseudocysts. Thus, amylase, viscosity, cytology, and tumor markers (including CEA) should be obtained from cyst aspirates when possible.

Pancreatic abscesses

Pancreatic abscesses are circumscribed intraabdominal collections of pus, usually within or in close proximity to the pancreas. In contrast to infected pancreatic necrosis, a pancreatic abscess contains little or no necrosis and typically presents later in the course of the illness, often more than 4 weeks after the onset of acute pancreatitis. Clinical and laboratory findings of acute pancreatitis have usually resolved before pancreatic abscess is detected. Because the infected collection is walled off and the surrounding tissue is viable, spread of infection to adjacent tissues is uncommon. Endoscopic or percutaneous drainage of pancreatic abscess is usually successful, although a minority of patients will require surgery. Endoscopic transpapillary drainage is also feasible when the abscess cavity communicates with the pancreatic duct [265].

Other local complications

Ascites and fistulae

Several processes may contribute to the formation of ascites in acute pancreatitis. Peritoneal inflammation resulting from chemical peritonitis usually generates a small amount of fluid. Attendant chronic liver disease may contribute varying amounts of ascites. Pancreatic ascites refers to the presence of large amounts of fluid rich in pancreatic secretions; it results from a communication between the pancreatic duct or a pseudocyst and the peritoneal cavity. Pancreatic ascites produces a gradual increase in abdominal girth, and is sometimes associated with subcutaneous fat necrosis. Because the pancreatic enzymes usually remain inactive, peritonitis is uncommon. The diagnosis should be suspected when ascites fails to respond to diuretic therapy and the serum amylase level is persistently elevated. Marked elevations of the ascitic fluid amylase level and ascites protein concentrations above 3 g/dL are typical of pancreatic ascites. The site of ductal disruption can sometimes be identified by CT or MRI, but ERCP is often required [210].

Three forms of treatment have been used to treat massive pancreatic ascites. Endoscopically placed pancreatic stents can be used to bridge the ductal disruption. Total parenteral nutrition together with administration of somatostatin or

octreotide has also been used, with or without paracentesis. A minority of patients will require surgical drainage or pancreatic resection. Endoscopic therapy appears to be more effective than medical therapy [266].

Pancreatic fistulae usually arise after a bout of alcoholic pancreatitis or from pancreatic pseudocysts, but also may form after pancreatic trauma, acute pancreatic duct disruptions, percutaneous catheter placement, or pancreatic surgery. Anterior pancreatic ductal discontinuities can generate ascites, whereas posterior disruptions may result in fistulae that burrow through to the skin or track through the retroperitoneum. Fistulae sometimes extend through the esophageal or aortic hiatus into the chest, producing pleural effusions or mediastinal collections rich in amylase. Internal fistulae may communicate with the colon, gallbladder, and small bowel. Fistulas to vascular structures such as the portal vein have rarely been reported, and are often associated with subcutaneous fat necrosis.

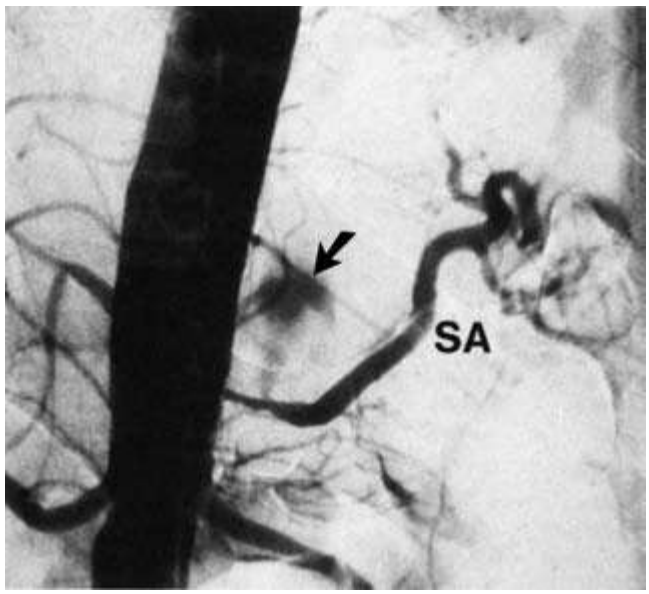
The fluid from a pancreatic fistula has high protein and amylase contents. The anatomy of an external fistula may be revealed by a fistulogram. Although ERCP is the most useful test for identifying an internal fistula, CT scanning may be useful for fistulae that communicate with the thoracic cavity. Spontaneous healing is more common for cutaneous fistulae than internal fistulae. Drainage of fluid collections by thoracentesis or paracentesis may help to heal serosal discontinuities. Reduction of pancreatic secretion by administering somatostatin analogues has been reported to promote the resolution of fistulae, particularly those with cutaneous communications. Stenting of the pancreatic duct or surgical resection, however, are usually required for internal fistulae. Pancreatic stents are most effective when they bridge the site of ductal disruption [261,262].

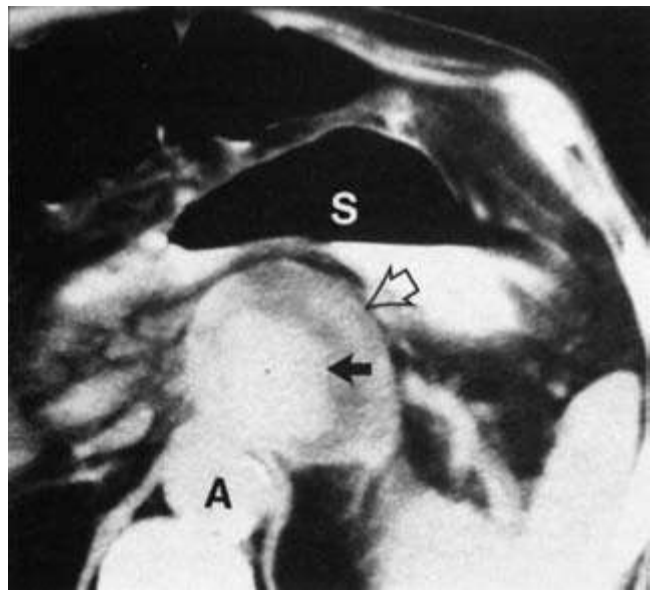
Vascular and splenic complications

Pancreatitis infrequently results in bleeding or thrombosis of peripancreatic vessels. The commonest venous complication of pancreatitis is occlusion of the splenic vein, which is adjacent to the posterior superior margin of the pancreas throughout most of its course. Splenic vein thrombosis results in splenomegaly, gastric varices, and rarely colonic varices. Occlusion of the superior mesenteric vein can also occur, causing mesenteric venous congestion and small bowel edema and ischemia. Severe pancreatic inflammation or a large pseudocyst may thrombose or compress these vessels. When acute thrombosis of these veins is detected thrombolytic therapy is sometimes considered, but there are few data regarding the safety of such therapy and the risk of retroperitoneal hemorrhage in patients with ongoing pancreatitis.

Arterial hemorrhage may also occur as a result of pancreatitis, and is a life-threatening event. This typically occurs when a pseudocyst erodes into a pancreatic artery, transforming the pseudocyst cavity into a pseudoaneurysm whose walls are partially formed by the artery and partially by the pseudocyst (Fig. 68.22). The splenic artery may be involved if the pseudocyst is in the pancreatic body or tail, whereas the gastroduodenal artery or branches of the pancreaticoduodenal arcade are typically affected in the head of the pancreas. If the pseudocyst communicates with the pancreatic duct, hemosuccus pancreaticus (or bleeding into the duodenum

(a)





(b)

Courtesy of Caroline Taylor, West Haven, CT.

through the pancreatic duct and ampulla) ensues. Diagnosis is made by CT scanning and angiography. The bleeding artery can often be treated by embolization, but sometimes requires surgical ligation and, occasionally, broad surgical resection. If hemorrhage is controlled angiographically, subsequent endoscopic treatment of the pseudocyst has been described [267].

Extension of a pseudocyst, or occasionally inflammation alone, from the pancreas into the spleen may lead to a splenic hematoma and rupture. This complication is most often associated with chronic disease and may present with abdominal pain that is referred to the left shoulder, fever, and an abdominal mass. Ultrasonography or CT suggests the diagnosis. Arteriography may demonstrate splenic artery pseudoaneurysms. Emergency splenectomy is required for splenic rupture, and prophylactic splenectomy has been advocated by some authors even when splenic pseudocysts are asymptomatic [268]. Splenic pseudocysts have been successfully drained endoscopically.

Gastrointestinal obstruction

Severe acute pancreatitis may result in compression of the duodenum, with gastric outlet obstruction. Bile-duct obstruction may also occur. These forms of gastric or biliary obstruction will usually resolve unless there is underlying chronic pancreatitis or pseudocyst.

It is common for pancreatic inflammation to extend to the transverse colon and splenic flexure. Obstruction secondary to spasm and edema may cause the classic colon cutoff sign, with gas present in the right colon but absent distal to the region of obstruction. This finding is seen in 1%–10% of patients with acute disease, and cecostomy is occasionally required to prevent colonic perforation in patients with colonic obstruction and progressive dilation of the proximal colon [269]. Extension of pancreatic inflammation may lead to persistent colonic strictures, fistulas, or even perforation. During surgery for acute pancreatitis, especially when performed for debridement, the colon is particularly susceptible to devitalization and subsequent perforation. Rarely, erosion into colonic blood vessels may result in acute lower gastrointestinal hemorrhage or inferior mesenteric vein thrombosis and colonic infarction.

Systemic complications

Systemic complications of acute pancreatitis may be caused by the direct toxicity of circulating activated pancreatic enzymes, the systemic inflammatory response to pancreatic injury and necrosis, circulating endotoxins arising from bacterial translocation from the gut, or combinations of these factors. Organ failure can result, and is usually manifested as respiratory insufficiency, vascular complications including shock, a sepsis-like syndrome, or disseminated intravascular coagulation, and renal failure. Gastrointestinal bleeding and confusion or coma may also occur, and MODS may develop. Organ failure is seen uncommonly in interstitial pancreatitis, but develops in about 50% of patients with pancreatic necrosis, and is an independent predictor of mortality [248]. Early mortality in acute pancreatitis is often due to multiple organ failure, whereas late mortality is more often related to infection.

Multiple organ dysfunction syndrome (MODS) and systemic inflammatory response syndrome (SIRS)

Organ failure or dysfunction in acute pancreatitis is associated with high levels of circulating tumor necrosis factor and IL-6 [270], and systemic activation of macrophages and the complement system [271]. Respiratory failure is the most common form of organ dysfunction in acute pancreatitis, followed by vascular and renal complications. Consensus criteria for the diagnosis of organ failure or dysfunction were proposed in 1992 by the Atlanta Symposium on Acute Pancreatitis, which defined organ failure as either absent or present in a variety of physiological systems (Table 68.3) [9]. Marshall and colleagues subsequently proposed a scoring schema for "multiple organ dysfunction syndrome" (MODS) that grades the degree of organ dysfunction in six physiological systems. The function of each organ system is scored from 0 to 4, with a score equal to or greater than 2 indicating dysfunction of that organ system [272]. The resulting Marshall score, which has been validated and widely applied to a range of critical illnesses, can range from 0 to 24. Scores greater than 20 have been associated with intensive care unit (ICU) mortality rates of 100% [272]. When applied to acute pancreatitis, investigators have modified the Marshall system, omitting the hepatic dysfunction scale because hyperbilirubinemia in gallstone pancreatitis is more often due to biliary obstruction than hepatic failure. The MODS scoring system used in pancreatitis trials is shown in Table 68.3 [249].

Predictors of MODS include the admission APACHE II score, the serum CRP level at 48 h, the presence of pancreatic necrosis, and the presence of SIRS (Table 68.6) [247–249].

Organ dysfunction is a dynamic process that is reversible in some patients. The time course of organ dysfunction predicts mortality from acute pancreatitis. Those patients whose organ dysfunction resolves in the first week do well, whereas those with deteriorating organ dysfunction have a mortality rate of over 50% [247]. Similarly, SIRS may also be transient or persistent. In one large series, the prevalence of SIRS among patients with acute pancreatitis was 21% on hospital admission, and 18% had persistent SIRS at 48 h. Persistent SIRS was associated with development of MODS and mortality from acute pancreatitis [249].

Respiratory failure

The most common form of organ failure in acute pancreatitis is pulmonary insufficiency due to the adult respiratory

distress syndrome (ARDS). This hypoxemic state is associated with a normal pulmonary venous wedge pressure, decreased pulmonary compliance, and pulmonary capillary injury. Obese patients and those with hypertriglyceridemia are at increased risk for developing this complication. In patients with severe ARDS, respiratory support with positive end-expiratory pressure is required.

Pulmonary function may be further affected by pleural effusions and decreased diaphragmatic movement due to ascites or retroperitoneal inflammation. The contribution of decreased diaphragmatic movement is unclear, but may be a factor in the increased risk of a pulmonary death in those with acute pancreatitis and obesity. Effusions are reported in 4%–17% of patients with acute pancreatitis; up to 50% may be associated with pseudocysts or pancreatic fistula. Most effusions are found on the left side or are bilateral, and most resolve spontaneously [229]. The early appearance of effusion has been associated with more severe disease. Thoracentesis is suggested when needed for diagnosis, to exclude infection, or when the size of the effusion results in respiratory compromise. Marked elevation of the pleural fluid amylase level may suggest an underlying pancreatic fistula, which may respond to antisecretory or endoscopic therapy.

Fat necrosis

Clinically evident fat necrosis in regions distant from the pancreas is seen in less than 1% of patients with acute pancreatitis. Pancreatic enzymes have been detected in areas of fat necrosis and are presumably responsible for initiating this injury. The initial injury may arise from the cleavage of adipocyte plasma membrane glycerosphingolipids by phospholipase A. Adipocyte-associated or circulating lipase activities may then enter the cell and convert triglycerides to monoglycerols and toxic free fatty acids. Several clinical syndromes are associated with fat necrosis. Cutaneous necrosis generates widely disseminated, raised, erythematous, and tender nodules of less than 2 cm in diameter. The process is frequently associated with fever and eosinophilia. The nodules typically resolve in days to weeks; however, some may rupture and heal with hyperpigmentation. Fat necrosis may affect the marrow cavity and lead to vascular damage and bone infarction. The typical bone lesions are frequently painless, osteolytic, develop 3–6 weeks after the onset of pancreatitis, and involve the ends of long bones such as the femur. Synovial pad fat necrosis may be associated with arthritis. The increased amounts of free fatty acids recovered from such joints may initiate this inflammatory process. Fat necrosis may rarely affect the middle ear.

Other systemic complications

Confusion and coma can occur and may be due to cerebral edema. Gastrointestinal hemorrhage may be caused by mucosal erosions and ulcerations, gastric varices, colonic varices, or a pancreatic pseudoaneurysm, as described above (see "Vascular and splenic complications"). Temporary blindness has been reported in pancreatitis and may be attributed to the retinal ischemia induced by leukocyte emboli.

Acute treatment

The treatment of acute pancreatitis is largely supportive. Pancreatitis patients are often in critical need of such care, and appropriate treatment is frequently lifesaving. Aggressive fluid replacement, management of pain and nausea, prompt identification and treatment of complications, nutritional support, and prophylaxis and treatment of infection are important elements of supportive care.

Some treatments have lost favor due to lack of convincing efficacy. These include peritoneal lavage and nasogastric suction. The use of nasogastric suction in the past was based on the unproven concept that removing the acid-dependent stimulation of the pancreas would allow the inflamed organ to rest and promote recovery. However, clinical trials showed no benefit from nasogastric suction for treatment of underlying pancreatitis. Nasogastric suction should be reserved for patients with persistent emesis, and the occasional patient with evidence of gastric or colonic obstruction complicating acute pancreatitis.

Supportive care includes careful observation of the patient. Regular assessment of vital signs and oxygen saturation should be a routine part of care. Decreased urine output, hemodynamic instability, or worsening oxygen saturation should lead to prompt evaluation and treatment, perhaps in an ICU.

Parenteral narcotics are often required for treatment of pain in acute pancreatitis, and meperidine has traditionally been the narcotic of choice because it does not cause pancreatitis or significantly alter sphincter of Oddi function [273]. However, meperidine is a less effective analgesic than many other narcotics, and accumulation of meperidine metabolites may cause paranoia, psychosis, or seizures. Morphine administration is discouraged in acute pancreatitis because it can cause sphincter of Oddi spasm and, rarely, pancreatitis. The effects of other narcotics on the sphincter of Oddi are less well studied, but hydromorphone or other agents may be appropriate in some cases, particularly if meperidine is ineffective, large doses are required, or prolonged use of narcotics is anticipated.

Fluid and electrolyte replacement

The cornerstone of supportive therapy is maintenance of an adequate intravascular volume. The analogy between the injury of severe pancreatitis and a burn is a useful one: pancreatitis often leads to "third spacing" of fluid and intravascular volume depletion. This may in turn worsen pancreatic

perfusion and exacerbate the pancreatitis. Hemoconcentration is associated with the development of pancreatic necrosis. The clinician should regularly reassess intravascular volume and aggressively replace fluids and electrolytes to avoid volume depletion. Often such assessment is made on the basis of urine output and vital signs. An elevated hematocrit or renal insufficiency may be signs of inadequate volume replacement. In severely ill patients, central venous pressure monitoring may be useful. Although dextrans have been used to expand intravascular volume and enhance pancreatic blood flow, their use has not been widely accepted.

Metabolic abnormalities

Hyperglycemia is present in some patients with acute pancreatitis. Tight glycemic control (blood glucose 80–100 mg/dL) has been associated with improved outcomes in critically ill patients [274], mainly due to decreased rates of organ dysfunction and infection. Although specific data are not available, tight glycemic control may be of benefit in severe acute pancreatitis as well. However, limited glucagon and glycogen reserves, especially in alcoholics, diminish the ability of pancreatitis patients to respond to iatrogenic hypoglycemia.

Serum calcium levels may be decreased during acute pancreatitis, and levels below 7.5 mg/dL are associated with a poor prognosis. Factors that account for this decrease are sequestration of calcium by free fatty acids that have been generated by peritoneal fat necrosis, and dilution by intravenous administration of calcium-poor fluids. In addition, hypoalbuminemia may result in low total serum calcium with normal serum ionized calcium. Humoral factors such as parathyroid hormone resistance associated with hypomagnesemia, and hypersecretion of calcitonin and glucagon have been implicated in hypocalcemia, but are unlikely to play a major role. Calcium should be slowly administered to patients with decreased ionized serum calcium.

Hyperlipidemia may lead to pancreatitis, accompany alcoholic pancreatitis, or be a consequence of acute pancreatitis. Therapy should generally not be instituted for hyperlipidemia encountered during acute pancreatitis, but values should be remeasured after recovery. One exception is patients with severe pancreatitis and respiratory failure. In this subgroup, and in the occasional patient with extreme hyperlipidemia, lowering serum triglycerides with plasmapheresis may be useful [275].

Inhibition of enzymes, secretion, and inflammation

Pharmacological therapy could theoretically be used to limit the severity of pancreatitis at several levels: by inhibiting active pancreatic enzymes, inhibiting pancreatic secretion, or interrupting the inflammatory cascade. The first agents to be tested extensively in humans were drugs that inhibit activated pancreatic enzymes. Of these "protease inhibitors" the best studied is gabexate mesilate, which is not available in the United States.

Most studies of gabexate have shown a benefit in acute pancreatitis that did not reach statistical significance. Two metaanalyses evaluating controlled clinical trials of gabexate in acute pancreatitis found that gabexate does not reduce mortality from acute pancreatitis, but does appear to reduce the incidence of complications by about 30% [199,276]. Although a subsequent trial showed decreased early mortality in patients with severe disease, it is unlikely to alter the basic conclusions of the metaanalyses, which drew on studies enrolling over 800 patients with acute pancreatitis [277]. The lack of a more decisive clinical effect is consistent with the fact that activated pancreatic enzymes play their most important role early in the course of pancreatitis, before the patient presents for treatment.

Somatostatin and octreotide, two agents that inhibit pancreatic secretion, have also been extensively studied in clinical trials. When only randomized controlled trials were considered, metaanalysis showed a statistically significant reduction in mortality with somatostatin therapy, and a lesser benefit with octreotide that did not reach statistical significance [278]. Curiously, despite their effect on mortality, neither agent was shown to decrease complication rates. The lack of demonstrated benefit with octreotide therapy may reflect its effects on sphincter of Oddi function and pancreatic blood flow. Although somatostatin appears to have a significant impact on mortality, it is not available in the United States.

Severity of the systemic immune response, as measured by blood levels of circulating proinflammatory cytokines, correlates with the development of local and systemic complications in pancreatitis. The inflammatory response often continues to increase after the patient is hospitalized, suggesting that pharmacological blockade of proinflammatory cytokines soon after hospital admission could ameliorate the consequences of pancreatitis. Although animal studies support this hypothesis, an inhibitor of platelet-activating factor (a proinflammatory cytokine) tested in a large clinical trial did not have a significant effect on complication rates or mortality [279]. Experimental studies suggest that specific cytokines may promote injury in distinct tissues. Therefore, a different cytokine inhibitor or a combination of inhibitors might be needed to achieve benefit.

Enteral and parenteral nutrition

One longstanding tenet of supportive treatment has been to avoid pancreatic stimulation by giving the patient nothing to eat during their acute illness. Patients with mild disease who rapidly improve and resume oral intake require no special form of nutritional support, but those with more protracted disease are generally given nutritional therapy.

Controlled trials of total parenteral nutrition (TPN) have shown little or no benefit for patients awaiting surgery or undergoing chemotherapy. Although there are few controlled data for pancreatitis, some retrospective studies suggest that

pancreatitis patients given early parenteral hyperalimentation are at increased risk for complications such as sepsis and pancreatic infection. Although intravenous lipid infusion does not stimulate pancreatic secretion, it can produce hyperlipidemia that can then trigger further pancreatitis. Because TPN-induced elevations of the triglyceride level have been reported to cause pancreatitis, it seems prudent to monitor triglyceride levels and attempt to keep them below 500 mg/dL in pancreatitis patients receiving TPN [280].

A growing body of evidence suggests that enteral feeding is safe in pancreatitis, and preferable to parenteral nutrition. Oral feeding stimulates pancreatic secretion, but feeding directly into the distal small bowel may result in negligible pancreatic stimulation [281]. Theoretically, enteral feeding could limit the changes in gut mucosal integrity seen in pancreatitis, with a resultant decrease in bacterial translocation, systemic immune response, and pancreatic infection. These considerations have led to controlled trials of enteral vs parenteral nutrition in pancreatitis.

In one randomized study, enteral feeding through a nasojejunal tube was compared with TPN in patients with mild acute pancreatitis mostly attributed to alcohol [282]. Enteral feeding was begun within 48 h of admission and was well tolerated in all cases. There was no significant difference between the two groups in major endpoints, including time to normalization of serum pancreatic enzyme levels, resolution of pain, time to oral feeding, or incidence of infection. Several patients tolerated enteral feeds well despite failing subsequent trials of oral intake, or had recurrent pancreatic symptoms when the tip of the enteric feeding tube fell back into the stomach.

Two other studies have randomized patients with severe disease to TPN or early enteric feeding. In both studies enteric feeding was safe and less costly than TPN, and was associated with improved outcomes as determined by either laboratory markers of inflammation or the incidence of infections and other complications [283]. Patients with clinical evidence of ileus generally tolerated enteric feeding well. An additional study showed no benefit of enteral feeding ascertained by markers of the immune response or intestinal permeability, but tube dislodgement was common in this study, and patients received only 20% of their predicted caloric requirements [284].

Enteral feeding can be recommended in acute pancreatitis, especially when it is unlikely that the patient will quickly resume oral intake. Early initiation of nasojejunal feeding (within 48 h of admission) is safe and may improve the course of the illness in patients with severe disease. The major impediment to this therapy is the practical difficulty of placing a nasojejunal tube. Methods for simple enteric feeding tube placement have been described, including both fluoroscopic techniques and bedside transnasal endoscopy [285]. Isocaloric full-strength formula can be used, beginning at 25 mL/h, and increasing the rate every 4 h until the patient's target rate is met. Feeding is generally successful even in the presence of ileus, but high gastric residuals or symptoms of nausea and abdominal fullness may prompt a decrease in the infusion rate.

Nasogastric tube feeding is a simpler alternative for enteral nutritional support. Two small randomized controlled studies of nasojejunal vs nasogastric feeding in patients with severe acute pancreatitis, many of whom were in an ICU, showed no difference in patient outcomes [286,287]. Because intragastric feeding does stimulate subsequent pancreatic secretion in healthy persons, it is unclear why nasogastric tube feeding would be well tolerated in acute pancreatitis. Patients with severe acute pancreatitis may have a "stunned pancreas" that is less responsive to stimulation.

When the patient is ready for oral feeding tradition holds that they should be started on a low-fat diet, but there is little evidence that this restriction affects recovery. Indeed, lumenal amino acids are also potent stimulants of pancreatic enzyme secretion. Probably more important than fat restriction is the subjective response of the patient to feeding. The most reliable marker for beginning oral feeding is hunger. Steady improvement in pain and tenderness allowing discontinuation of parenteral pain medication is also a useful indicator. Persistently abnormal serum enzymes or CT scans in the absence of symptoms or complications should not dissuade the clinician from feeding a hungry patient. There is no reason to believe that the mechanical consistency of the food is important in refeeding.

A significant minority of patients will have pain with refeeding, especially those with necrotizing pancreatitis. In one series, pretreatment with lanreotide (a somatostatin analogue), 30 mg intramuscularly, markedly decreased the rate of refeeding pain in patients with necrosis compared with historical controls [288]. Prospective controlled study of this strategy is warranted.

Antibiotic prophylaxis

Infection of pancreatic necrosis is a life-threatening complication and a major risk factor for death from pancreatitis [289]. Strategies for the prevention of infected necrosis have been evaluated, including systemic antibiotic prophylaxis and selective decontamination of the gut.

Older studies of antibiotics to prevent pancreatic infection found no benefit. These studies probably enrolled many patients at low risk for infection, and did not select antibiotics based on their ability to penetrate pancreatic tissue. Subsequent investigations demonstrated that penetration of pancreatic tissue by ampicillin and aminoglycosides is poor, whereas imipenem–cilastatin, mezlocillin, third-generation cephalosporins, metronidazole, and quinolones exhibit moderate to excellent penetration [290].

Prospective randomized studies of antibiotics known to penetrate necrotic pancreatic tissue have demonstrated bene-

fits for prophylactic intravenous antibiotic therapy in patients with necrosis. Prophylactic imipenem–cilastatin, cefuroxime, and a combination of ceftazidime, amikacin, and metronidazole have been tested against placebo, and each regimen resulted in a significant reduction in the incidence of infectious complications [291,292]. These studies have been criticized for the absence of physician blinding, frequent crossover between study groups, and frequent use of off-protocol antibiotic regimens. Only the cefuroxime study showed a significant reduction in mortality, but had a high rate of nonpancreatic and staphylococcal infections, and did not demonstrate a significant reduction in the incidence of pancreatic infections. Two metaanalyses of antibiotic prophylaxis concluded that prophylaxis decreases sepsis and mortality in patients with necrosis [293,294]. In one comparative study, pefloxacin was less effective than imipenem–cilastatin for prevention of infectious complications. In a randomized study comparing early (at admission) vs late (> 48 h after admission) initiation of prophylactic antibiotics, there was a statistically significant benefit from early initiation of treatment, with pancreatic infection rates of 13% and 31% in the early and late groups, respectively [295].

The first double-blind randomized controlled trial of prophylactic antibiotics was published in 2004, comparing a 21-day course of intravenous ciprofloxacin and metronidazole with placebo in patients with severe acute pancreatitis. A total of 114 patients were enrolled, the majority of whom had pancreatic necrosis. Patients were switched to open antibiotic treatment if they developed new sepsis or SIRS, new MODS, documented pancreatic or extrapancreatic infection, or an increased serum CRP with clinical suspicion of infection; 28% of the treatment group and 46% of the placebo group were switched to open antibiotic treatment. On an intention-to-treat basis, infected necrosis developed in 12% of the antibiotic group versus 9% of the placebo group. The commonest bacteriological isolates from infected necrosis included enteric organisms and *Staphylococcus epidermidis*. Mortality was similar in both groups (5% and 7%) [296].

These data have renewed the controversy surrounding prophylactic antibiotic administration in severe acute pancreatitis. It is unclear whether antibiotics should be initiated in all patients with severe acute pancreatitis, or only "on demand" in patients with SIRS, MODS, documented infection, or clinically suspected infection [296]. Until additional double-blinded randomized studies are available, antibiotic prophylaxis or "on-demand" use of antibiotics are both reasonable strategies. Patients with necrosis documented by CT or, in the absence of early contrast-enhanced CT, patients with severe pancreatitis (who are at highest risk for necrosis) should be treated. If prophylactic treatment is given, it should generally be started within 48 h of admission and continued for 2–3 weeks, and imipenem–cilastatin (500 mg every 8 h) is probably the most effective agent. Unfortunately, prophylactic antibiotics do not eliminate the risk of infected necrosis. Large series of patients treated with prophylactic antibiotics show an incidence of infected necrosis as high as 32%, with a shift toward gram-positive and fungal infections [255]. Fluconazole penetrates pancreatic tissue [297] but its role in the prophylaxis of pancreatic fungal infections is unproven. Methods for the diagnosis of infected pancreatic necrosis are discussed earlier (see "Complications" above).

Other strategies for prevention of infected pancreatic necrosis

An alternative to systemic antibiotic prophylaxis is "selective decontamination" of the gastrointestinal tract with lumenal antibiotics. The rationale for this approach is the finding that bacterial translocation from the gut is the likely source of infection in pancreatic necrosis [253]. Studies in animal models of severe pancreatitis show a benefit from intralumenal antibiotics and intestinal lavage. One large controlled clinical trial has tested this prophylactic strategy; patients with severe pancreatitis were randomized to receive no antibiotic prophylaxis or colistin sulfate (200 mg), amphotericin (500 mg), and norfloxacin (50 mg) orally every 6 h, and in a rectal enema daily. Intravenous cefotaxime was also given until gram-negative bacteria were eliminated from the mouth and rectum. The incidence of pancreatic infection was halved by selective decontamination, and mortality was significantly decreased as well [254]. The complex study regimen may be difficult to introduce in some practice settings, and further investigation of selective decontamination is needed.

Probiotic administration has been suggested as a potential method of preventing infected necrosis, but data are limited.

Treatment of infected pancreatic necrosis

As discussed earlier in this chapter, the diagnosis of infected pancreatic necrosis should be entertained in patients with systemic signs of infection, or in patients with persistent or worsening organ failure despite supportive care. Diagnosis requires a high level of suspicion. Available noninvasive laboratory and imaging tests do not reliably exclude infection, and CT-guided aspiration of necrotic areas for Gram stain, fungal stain, and cultures are the most important diagnostic modalities.

Anecdotal reports suggest that an occasional patient with infected necrosis will survive with antibiotic treatment alone [298]. However, antibiotics alone are generally inadequate for treatment of documented infected necrosis, and the infected necrotic material should be removed. Prompt surgical debridement has been the standard therapy, and repeated reexploration for further debridement is often necessary. This treatment results in mortality rates of between 20% and 60% [299]. Better surgical outcomes are in part associated

with changes in technique, including open packing of the wound and prolonged postoperative lavage.

Percutaneous drainage of infected necrosis was long thought to be an inadequate therapy, because the solid necrotic material would not drain out through small-caliber percutaneous catheters, and the drainage tube would only serve to introduce other organisms into the necrotic debris. However, reports have demonstrated that percutaneous catheter drainage can be effective [300,301]. In contrast to percutaneous treatment of pseudocysts or pancreatic abscesses, repeated interventions and aggressive techniques are required adequately to remove the infected material. Techniques may include placement of multiple large-bore (28-French) drainage tubes, frequent bedside catheter irrigation, periodic vigorous manual irrigation under fluoroscopic or CT guidance, and endoscopy of the percutaneous catheter tract for removal of debris using jet irrigation, forceps, and snares. Reported mortality rates of 15%–20% from expert centers compare favorably with surgical series. Complications include hemorrhage from retroperitoneal vessels, and patients with persistent pancreatic sepsis requiring surgery had a high mortality rate.

Endoscopic drainage of infected necrosis has also been described, in patients whose infection occurs in the setting of organized pancreatic necrosis (typically at least 2–3 weeks into the course) [259,302]. An aggressive endoscopic approach is necessary, as placement of a single plastic stent into an infected necrotic collection will not result in adequate drainage or allow debridement of the necrotic tissue. In one series multiple collections were drained into the stomach or duodenum under EUS guidance; in addition to endoscopic placement of stents and lavage catheters, cyst-enterostomies were dilated with large-caliber balloons to permit direct endoscopy of the necrosis cavity with endoscopic debridement [303]. Endoscopic debridement may be repeated daily or weekly. Outcomes in small series from expert centers compare favorably with the larger published surgical experience, although success is lower than for endoscopic drainage of pseudocysts [302]. Endoscopists and radiologists undertaking drainage of pancreatic necrosis should be prepared to perform repeated interventions over time as necessary to remove necrotic material and ensure adequate drainage.

Drainage of sterile necrosis

The role of surgery in sterile necrosis has been debated. Although routine surgical debridement of sterile pancreatic necrosis was advocated in the past, the weight of available evidence does not show a benefit from surgery over supportive medical care [304]. Nevertheless, intervention may be warranted in a small subset of patients in whom sterile necrosis is associated with either a deteriorating course despite maximal supportive care, or prolonged organ failure [305]. In such patients the percutaneous and endoscopic techniques described above are often appropriate as well.

Some patients with sterile necrosis require intervention not because of organ failure or an ongoing systemic inflammatory response, but because of recurrent pancreatic symptoms and an enlarging collection with attempts at refeeding. This is particularly common in patients with "central necrosis" (extensive necrosis of the pancreatic body) and is usually associated with a persistent disruption of the pancreatic duct, resulting in an isolated pancreatic tail and ongoing leakage of pancreatic juice from the disruption. Internal drainage of the collection may suffice, but resection of the pancreatic tail is required in many cases [301,306]. Drainage of sterile necrosis may also be required in patients with gastrointestinal obstruction caused by the necrotic collection.

Urgent ERCP and EUS in gallstone pancreatitis

Persistent bile-duct stones are associated with more severe pancreatitis, and both surgeons and endoscopists have investigated the theory that prompt relief of ampullary obstruction by removal of an impacted stone would decrease the severity of gallstone pancreatitis. Although studies of urgent surgery have yielded disappointing results, endoscopic studies have identified subgroups of patients who benefit from urgent ERCP.

Several randomized studies have assessed the value of urgent ERCP in patients with gallstone pancreatitis. The first, performed in the United Kingdom, found that ERCP within 2 days of presentation decreased the complication rate of gallstone pancreatitis [307]. Sphincterotomy was done only if stones were present in the ampulla or bile duct. The benefit was limited to the subset of patients who were predicted to have severe pancreatitis on initial assessment using the modified Glasgow criteria (Table 68.5). These results suggested that urgent ERCP could alter the course of acute gallstone pancreatitis.

A similar study subsequently reported from Hong Kong also found a decreased complication rate when urgent ERCP was performed and sphincterotomy was done for ampullary or ductal stones [144]. This study also showed that benefit was limited to patients predicted on admission to have severe pancreatitis, using the simpler urea–glucose criteria. The Hong Kong study included some patients with other causes of pancreatitis, and probably included more patients with primary pigment stones of the bile duct. In contrast to the British study, the benefit of ERCP appeared to be largely due to prevention of bacterial cholangitis rather than amelioration of pancreatitis.

Both of these studies found a benefit in patients predicted to have severe pancreatitis and showed that ERCP can be safely performed in this setting. It remains unclear if the benefit was the result of a decrease in the severity of pancreatitis or to treatment and prevention of cholangitis. The pancreas was not directly imaged by CT to assess the severity of pancreatitis in these studies. There was no evidence that ERCP could prevent a predicted mild episode of pancreatitis from progressing in severity, and there were no statistically

significant changes in survival. A third large study showed a significant improvement in mortality with early ERCP and sphincterotomy, but this was only published in abstract form [308].

A fourth study with a similar design from Germany showed a trend toward higher mortality and more severe complications in patients undergoing early ERCP [309]. This study excluded patients with a serum bilirubin above 5 mg/dL, probably excluding many patients with persistently impacted stones while including patients with milder disease and nonobstructing ductal stones. Because nonobstructing stones theoretically have little effect on either the development of cholangitis or the severity of pancreatitis, this study probably excluded those patients most likely to benefit from urgent ERCP. Unfortunately, none of these studies reported the incidence of impacted ampullary calculi. Further studies using noninvasive methods to visualize ampullary stones and grade the severity of pancreatic inflammatory changes may shed more light on the benefit achieved by ERCP and sphincterotomy.

When should the clinician consider urgent interventions to diagnose and remove bile-duct stones in patients with acute pancreatitis? The clearest indication is the presence or suspicion of biliary sepsis. Anicteric patients with mild pancreatitis and no signs of cholangitis are unlikely to require urgent ERCP. Jaundiced patients and those with predicted severe pancreatitis, especially those who fail to improve over the first 12–24 h of observation, may benefit from prompt bile-duct evaluation. In these patients, newer and less invasive methods of demonstrating ductal or ampullary stones (such as MRCP, helical CT, and endoscopic ultrasound) will probably be helpful in choosing patients who should undergo urgent ERCP [237]. A randomized prospective study comparing EUS and ERCP showed that urgent EUS could replace diagnostic ERCP in acute biliary pancreatitis, with therapeutic ERCP reserved for those patients with persistent bile-duct stones. Stone detection rates were higher in the EUS group, and there was a trend toward decreased morbidity in the EUS group [310].

Traditionally, cannulation of the pancreatic duct has been avoided when possible in patients with acute biliary pancreatitis undergoing ERCP. Yet some experts have advocated intentional visualization of the pancreatic duct early in the course of severe acute pancreatitis, for identification and endoscopic treatment of pancreatic duct disruptions. However, some disruptions resolve spontaneously [250], and instrumentation may introduce infection into a previously sterile collection. Controlled data evaluating this strategy are needed before it can be generally recommended. Similarly, a strategy of early ERCP and sphincterotomy in all patients with biliary pancreatitis cannot be generally recommended.

Preoperative ERCP in mild gallstone pancreatitis

Most patients with gallstone pancreatitis rapidly improve with supportive management, and by the time of their cholecystectomy only a minority have bile-duct stones. The bile duct should be imaged in such patients, and the choice of imaging technique depends on the likelihood of finding a bile-duct stone, the surgeon's ability to extract bile-duct stones laparoscopically, and the confidence of the biliary endoscopist.

Patients with gallstone pancreatitis whose serum liver tests and pancreatic enzyme levels steadily fall after admission have a low (8%) incidence of bile-duct stones [228], and are best evaluated with intraoperative cholangiography (IOC). Patients in whom any of these chemistries increase in the first 48 h of admission, and patients with a dilated bile duct on ultrasound, have an intermediate (30%) incidence of ductal stones. These patients may also best be evaluated with intraoperative cholangiography, depending on the comfort and skill of the available surgeon and endoscopist. Preoperative ERCP, MRCP, or EUS may also be appropriate in this patient group.

A randomized study compared preoperative ERCP with IOC in patients with mild to moderate biliary pancreatitis. Only patients with risk factors for retained ductal stones (bile-duct dilation, elevation of the serum bilirubin, or persistent hyperamylasemia) were enrolled. Patients with severe pancreatitis and those with cholangitis were excluded. Only 24% of patients in the IOC group had bile-duct stones and required postoperative ERCP. Patient outcomes were similar in the two groups. Hospital stay was longer and treatment costs were higher in the preoperative ERCP group [227].

Direct visualization of a ductal stone on ultrasound, CT, MRI, or EUS establishes a high risk (60% or greater) of a bile-duct stone in gallstone pancreatitis, and such patients, as well as those with persistent jaundice, may reasonably undergo preoperative ERCP.

Sphincterotomy as sole therapy for gallstone pancreatitis

Endoscopic sphincterotomy usually eliminates the common channel between the bile duct and pancreatic duct, which afterwards enter the duodenum at slightly different locations. Sphincterotomy appears to prevent recurrence of gallstone pancreatitis in patients whose gallbladder remains in place. At least 15% of patients treated in this fashion will subsequently develop other complications of gallstones, however, including biliary obstruction, cholangitis, and acute cholecystitis [311]. These complications are commonest within 6 months of sphincterotomy but may occur years later. In addition, a small percentage will develop stenosis of the sphincterotomy site. Cholecystectomy thus remains preferable to sphincterotomy in patients with uncomplicated pancreatitis who are fit for surgery. When the risks of cholecystectomy are high (as in patients with unstable cardiovascular disease or advanced cirrhosis), endoscopic sphincterotomy is a reasonable therapeutic alternative.

69 Chronic pancreatitis

Chung Owyang, Matthew J. DiMagno

Incidence and prevalence, 1812
Etiology, 1812
Clinical presentation, 1821
Pathomechanism of symptoms, 1822
Diagnosis, 1825
Complications, 1832
Treatment, 1834

The terminology surrounding the classification of inflammatory disease of the pancreas is confusing and is based on both clinical and morphological criteria. Since the 1970s, multiple classifications have been proposed. Differentiation by etiology allows for the prediction of the factors responsible for pancreatitis but gives little information on potential overlapping pathophysiological mechanisms. Clinical and pathological classifications by themselves have prognostic implications, with fulminant or hemorrhagic pancreatitis having a poor prognosis and edematous pancreatitis being associated with a good prognosis; only in a minority of patients is histological information ever obtained, however, and clinical classifications are not helpful pathophysiologically. In 1963, a symposium on pancreatitis was held in Marseilles, France, in which a clinical classification of pancreatitis was proposed, and this classification has since been widely used [1]. According to the Marseilles classification, pancreatitis can be divided into acute and chronic, with both types having relapsing and nonrelapsing varieties. The essential difference between acute and chronic pancreatitis is the presence of permanent and progressive morphological or functional damage in the latter. Both subtypes are further classified into relapsing and nonrelapsing varieties depending on their clinical presentation. In acute pancreatitis, if the primary causes or factors are eliminated, clinical and morphological restitution of the pancreas occurs. In contrast, in the chronic form, anatomic or functional pancreatic damage remains even after the primary causes are eliminated.

The major drawback of the Marseilles classification is the frequent inability to distinguish between acute and chronic forms of the disease based on their clinical presentation. This prompted two subsequent international symposia in 1983 [2] and 1984 [3] to discuss the classification of pancreatitis. Some minor modifications of the original Marseilles classification were proposed. The classification of pancreatitis should be reduced to include only acute and chronic forms because it is frequently difficult to distinguish between recurrent acute pancreatitis and recurrent attacks of chronic pancreatitis, and several years' follow-up may be needed. Accordingly, chronic pancreatitis is defined as an inflammatory disease of the pancreas characterized by persistent and often progressive lesions, whereas the lesions of acute pancreatitis regress when the cause is suppressed or removed. In an addendum, it was recognized that alcohol-induced pancreatitis may present acutely and is not inevitably progressive.

The second symposium at Marseilles [2] also proposed to distinguish obstructive chronic pancreatitis from other forms of chronic pancreatitis. Obstructive chronic pancreatitis is characterized by dilation of the ductal system, diffuse atrophy of the acinar parenchyma, and uniform fibrosis. In contrast to other forms of chronic pancreatitis, intraductal plugs or stones are usually rare or absent, and both structural and functional changes may improve when the obstruction is relieved. Based on morphology, biochemistry, molecular biology, and epidemiology, Sarles [4] reclassified chronic pancreatitis into four groups. The first and largest group, lithogenic pancreatitis (chronic calcifying pancreatitis), consists of five subgroups of stones: hereditary pancreatitis, transparent stones, nutritional pancreatitis, hypercalcemia pancreatitis, and pure calcium stones. The other three groups include obstructive pancreatitis, caused by obstruction of the pancreatic ducts preceding the onset of pancreatitis, with uniform distribution of the lesions caudal to the obstruction; inflammatory pancreatitis, which is characterized by diffuse fibrosis and the destruction of exocrine parenchyma with infiltration of mononuclear cells; and pancreatic fibrosis, characterized by silent, diffuse perilobular fibrosis.

A recent classification of chronic pancreatitis, the TIGAR-O system, incorporates new insights into genetic, environmental, immunological, and pathobiological risk factors associated with chronic pancreatitis [5]. The TIGAR-O etiological

Table 69.1 TIGAR-O System: etiological factors associated with chronic pancreatitis

Toxic-Metabolic	**Autoimmune**
Alcoholic	Isolated autoimmune chronic pancreatitis
Tobacco smoking	Syndromic autoimmune chronic pancreatitis associated with
Hypercalcemia	– Sjögren syndrome
Hyperlipidemia	– Inflammatory bowel disease
Chronic renal failure	– Primary biliary cirrhosis
Medications – phenacetin abuse	
Toxins – organotin compounds (e.g., dibutyltin dichloride)	
Idiopathic	**Recurrent and severe acute pancreatitis**
Early onset	Postnecrotic (severe acute pancreatitis)
Late onset	Recurrent acute pancreatitis
Tropical	Vascular diseases/ischemia
	Postirradiation
Genetic	**Obstructive**
Hereditary pancreatitis – cationic trypsinogen	Pancreas divisum
CFTR mutations	Sphincter of Oddi disorders (controversial)
SPINK1 mutations	Duct obstruction (e.g., tumor)
	Preampullary duodenal wall cysts
	Posttraumatic pancreatic duct scars

Adapted from Etemad and Whitcomb [5], with permission from Elsevier.

classification consists of six groups (see Table 69.1): Toxic-metabolic, Idiopathic, Genetic, Autoimmune, Recurrent and severe acute pancreatitis, and Obstructive. The relationships among the six groups remain unclear but conceptually, this system categorizes the groups by potential shared pathogenic mechanisms. Significant insight into shared mechanisms of disease has evolved with the identification of similar or different genetic mutations associated with conceptually different categories of chronic pancreatitis discussed in this chapter. As stated by the authors, "Further research is needed to determine the clinical and natural history of chronic pancreatitis developing in the context of various risk factors" [5].

Incidence and prevalence

The prevalence of chronic pancreatitis in autopsy materials ranges from 0.04% to 5% [6,7]. Most epidemiological data are obtained either from retrospective studies [8–10] or by calculations using data given in clinical material [11,12]. The only prospective study on the incidence and prevalence of chronic pancreatitis was performed in Copenhagen, Denmark, in 1978 and 1979 [13]. It showed an incidence of 8.2 new cases per 100 000 inhabitants per year, and a prevalence of 26.4 cases per 100 000 inhabitants. The epidemiological studies clearly demonstrate that there are enormous differences in the incidence rates between different areas. Alcohol consumption is considered to be the major factor in the development of chronic pancreatitis. This may well explain the low incidence (rate) of chronic pancreatitis in Japan, which has traditionally a very low alcohol intake. On the other hand, Switzerland has higher alcohol consumption than Denmark [14], but the incidence of chronic pancreatitis is lower in Switzerland than in Denmark.

Environmental or hereditary factors may influence susceptibility to alcohol-induced pancreatitis. Alternatively, this may be related to regional differences in diagnostic criteria for chronic pancreatitis. Figures for frequency of chronic pancreatitis differ markedly from one center to another; most likely, this does not reflect a real difference in frequency but points strongly to regional differences in patient selection and diagnostic criteria.

Etiology

Alcohol in Western societies (70%–80%) and malnutrition worldwide represent the major etiologies of chronic pancreatitis [15,16]. In addition, metabolic and mechanical disturbances, as well as hereditary disposition, have been implicated (Table 69.2).

Alcohol

Alcohol consumption is the major risk factor for chronic pancreatitis, but probably requires additional anatomic, environmental, or genetic cofactors to induce the disease because less

Table 69.2 Etiology of chronic pancreatitis

Trauma
Pancreatic divisum

than 10% of alcoholics develop pancreatitis [17]. In Western societies, about 70% of cases are caused by alcohol [18]. The incidence of pancreatitis found at autopsy in alcoholics is as high as 45–50 times the rate in nondrinking controls [19]. There is a linear relationship between the logarithm of the risk for development of chronic pancreatitis and the mean daily consumption of alcohol [20]. Furthermore, it has been demonstrated that the risk for abstainers is lower than the risk for people drinking a low quantity of alcohol (i.e., 1–20 g/day). Therefore, it appears that there is no statistical threshold for alcohol toxicity but a continuous spectrum of individual thresholds. This makes it difficult to distinguish between low-threshold, alcohol-induced pancreatitis and idiopathic pancreatitis. The duration of alcohol consumption is also important. For the same daily intake, the risk increases with duration [21], but the type of alcoholic beverages chosen and the pattern of drinking (weekend vs daily users) have no influence on the risk for development of chronic pancreatitis [22]. This concept, however, has been challenged [23].

In general, prolonged alcohol intake is required to produce symptomatic chronic pancreatitis (6–12 years), although the length of time required for histological damage in humans is unknown [24]. Clinically, alcoholic chronic pancreatitis is characterized by an initial period of recurrent acute attacks lasting 5–6 years, followed by the development of chronic pain, exocrine and endocrine insufficiency, or both. A natural history study [25] demonstrated a median time to exocrine insufficiency of 13 years in patients with alcoholic chronic pancreatitis and a median time to endocrine insufficiency of 20 years. Interestingly, not all patients with an acute episode of alcohol-induced pancreatitis progress to clinical chronic pancreatitis. It is generally accepted that at the time of the initial attack of pancreatitis, histological, chronic pancreatitis is already present. Two retrospective studies [26,27] reported that 15%–20% of patients who were followed for up to 30 years after an initial attack of alcoholic chronic pancreatitis did not develop pancreatic calcification or exocrine or endocrine insufficiency. The factors responsible for this variability in disease progression are not clear but do not appear to be caused by differences in avoidance of further alcohol. Patients with progressive disease were more likely to have more severe and more frequent acute clinical attacks of pancreatitis, and these patients frequently developed significant abnormalities affecting the main pancreatic duct.

A variety of studies provide evidence that one or more cofactors are necessary to sufficiently increase the risk (or lower the threshold) for alcohol to induce chronic pancreatitis. Kondo and colleagues [28] reported that the aberrant pancreas might not be susceptible to alcoholic pancreatitis. Anatomic differences in the aberrant pancreas, such as innervation and different ductal drainage, may explain the lack of damage after chronic alcohol ingestion. In addition, dietary factors may play a significant role. Both experimental and epidemiological studies indicate that the risk for alcohol-induced pancreatitis is higher in people with high-fat, high-protein diets. Severe focal lesions of chronic pancreatitis, however, were observed in rats fed higher amounts of fat, which resulted in striking potentiation of alcohol-induced pancreatic injury [29,30]. Observations from these experimental studies were supported by clinical and epidemiological studies. It has been observed in many European countries that alcoholics consuming a high-fat, high-protein diet are predisposed to chronic pancreatitis [6,31–33]. Durbec and Sarles [20] noted that the risk was less with average consumption of fat but was increased by both high (more than 100 g/day) and low (less than 85 g/day) daily fat intakes. Furthermore, the effects of alcohol, protein, and fat consumption appear to be additive. This may explain why chronic pancreatitis is more commonly observed in patients who drink more alcohol and eat more protein and fat than in controls [21]. Observations made in Europe, however, are not confirmed by studies reported from the United States and Australia [34–36]. It appears that whereas a high-fat or high-protein diet may predispose to pancreatitis, such a diet is not a prerequisite for the development of pancreatitis in chronic alcoholics. Differences in the quantity of alcohol and the type of fat consumed by various populations may explain some of these conflicting observations, but recent studies indicate that other factors may also play a role, including concurrent group B Coxsackie virus infection, genetic predisposition, and cigarette smoking.

Group B Coxsackie virus infection is a proposed and underexplored cofactor for alcoholic chronic pancreatitis. It is well known that Coxsackie virus causes necrotizing pancreatitis in humans. Experimental studies show that the virus causes acute pancreatitis in a virus titer-dependent fashion [37,38], which may progress to chronic pancreatitis when there is a lack of tissue repair, a defect associated with preferential activation of M1 macrophages and T helper type 1 cells rather than M2 macrophages and T helper type 2 cells [39]. Further, short-term (5–14 days) and subchronic (> 28 days) administration of oral ethanol potentiates virus-induced pancreatitis and impairs pancreatic regeneration following injury in a dose- and duration-dependent fashion [38]. Alcohol

may modify rather than trigger acute pancreatic injury, possibly by increasing tissue virus infection or replication, impairing tissue healing, and promoting chronic injury. Further research is needed to determine how group B Coxsackie virus infection occurs and increases the risk of clinical alcoholic chronic pancreatitis.

A strong genetic susceptibility factor for alcoholic chronic pancreatitis has not been identified [40], but information about the association between mutations of the serine protease inhibitor, Kazal type 1 (*SPINK1*) gene and alcoholic pancreatitis is conflicting [41–44]. The association of cystic fibrosis transmembrane conductance regulator (*CFTR*) mutations with alcoholic pancreatitis is uncertain; it is absent in several large studies [45–47] and present in 23%–40% of patients in large Italian [48], Spanish [49], and Japanese [50] studies. The latter three studies raise the possibilities that an increased frequency of *CFTR* mutations occurs in patients with idiopathic and alcoholic chronic pancreatitis, that there may be regional genetic differences in patients with alcoholic chronic pancreatitis, and, as reported by Casals and colleagues [49], that different *CFTR* mutational spectra may be present in patients with alcoholic vs idiopathic chronic pancreatitis. The Japanese study noted the rarity of cystic fibrosis in Japan (1 per 350 000 compared with 1 per 2500 in Western countries). In support of these data, Naruse and colleagues [51] showed in a pilot study that *CFTR* dysfunction (indicated by the finger sweat test) was present in 52% of patients with chronic pancreatitis (21 alcoholic and 4 idiopathic) compared with 16% of control subjects. It is not known whether mutations in the *CFTR* gene are associated with alcoholic chronic pancreatitis and whether the simple finger sweat test is clinically useful to determine *CFTR* dysfunction in patients with pancreatitis.

The pathogenic mechanisms of alcohol-induced chronic pancreatitis are uncertain. Results from a prospective clinicopathological study of alcohol-induced recurrent attacks of acute pancreatitis evolving to chronic pancreatitis [52] support the hypothesis of the necrosis–fibrosis sequence, originally proposed in 1946 by Comfort and associates [53]. Chronic alcoholism causes an increase in basal secretion of proteases, amylase, and lipase, and a decrease in trypsin inhibitor in rats [54]. Furthermore, an increased responsiveness of the pancreas to cholecystokinin (CCK) stimulation has been reported in dogs [55] and humans [56].

The augmented responsiveness of the exocrine pancreas may account for the high-protein, low-bicarbonate, and low-volume pancreatic secretory output after chronic alcohol consumption [57]. Theoretically, protein precipitates would be formed, particularly in areas of low flow rate such as the secondary pancreatic ducts. This may explain the frequent involvement of the secondary duct, with relative sparing of the main pancreatic duct, in early stages of chronic pancreatitis.

The discovery of a pancreatic stone protein (lithostatin) found in pancreatic juice and calculi has generated considerable interest because this protein is capable of inhibiting the formation of insoluble calcium salts in a supersaturated milieu [58,59]. Lithostatin is decreased in the pancreatic juice of patients with alcoholic pancreatitis and in some patients with nonalcoholic chronic pancreatitis [60]. Hence, it is conceivable that a deficiency of lithostatin may play an important role in the development of pancreatic calcification [58]. The importance of this protein remains unclear, however, because not all studies have shown a reduction in lithostatin in pancreatic juice from patients with chronic pancreatitis [61].

One report [62] showed that GP2, a protein found on the zymogen membrane that is secreted into the pancreatic duct by exocytosis, is a reproducible integral component of the protein plugs found in patients with noncalcific, chronic pancreatitis. On the other hand, lithostatin was found less frequently and in variable amounts. Interestingly, GP2 has significant homology with the urinary protein uromodulin (Tamm–Horsfall protein), which is involved in the formation of protein precipitates in urine. It has been suggested that GP2 may be involved in the formation of protein plugs in the pancreatic duct in patients with chronic pancreatitis.

In addition to hypersecretion of protein, the viscosity of pancreatic juice is enhanced in chronic pancreatitis because of a higher concentration of hexosamine [63]. There is a correlation between the concentrations of protein, hydrolytic enzymes, hexosamine, and viscosity [63]. Hyperviscosity of pancreatic juice may result in decreased flow and contribute to protein precipitation in chronic pancreatitis. Therefore, it appears that chronic alcoholism results in a number of changes in the pancreatic juice that create an environment that is conducive to the formation of intraductal protein plugs that block small ductules in a random fashion. Ductal blockade produces progressive structural abnormalities in the ducts and acinar tissue. In time, calcium is complexed to protein plugs, initially in small ductules and, eventually, in the main pancreatic duct. Progressive blockade results in injury and destruction of pancreatic tissue [64].

In addition to the perturbation in the content and secretion of pancreatic enzymes, chronic alcohol consumption also causes perturbation in the lysosomal enzymes; acid phosphatase was increased in cell fractions, and cathepsin B was increased in the mitochondrial–lysosomal fraction and the zymogen granule fractions of the pancreas from alcohol-fed rats [65]. Therefore, it is conceivable that alcohol produces pancreatitis by interfering with the intracellular transport and discharge of digestive enzyme, causing colocalization of digestive and lysosomal hydrolases, a condition that is conducive to the initiation of autodigestion. As evidence, in vitro studies showed that alcohol increased the sensitivity for intraacinar trypsinogen activation induced by cerulein hyperstimulation [66]. Furthermore, in vivo experimental acute pancreatitis studies showed that alcohol sensitizes rats to pancreatitis caused by CCK-8 and was associated

with upregulation of proinflammatory cytokines and chemokines [67]. In an experimental model leading to chronic pancreatitis, Deng and colleagues [68] confirmed not only the potentiating effect of alcohol (Lieber–DeCarli protocol) on CCK-8-induced acute pancreatic injury in rats but also that the onset of pancreatic fibrosis was accelerated by both ethanol exposure and the increased severity and duration of the pancreatitis trigger. These findings support the concept that ethanol plays a modifying rather than a triggering role in pancreatitis and that acute injury with persistent inflammation fosters fibrogenesis.

The biochemical mechanisms responsible for the occurrence of fibrosis in chronic pancreatitis are also unclear. Recent evidence suggests that pancreatic stellate cells (PSCs) undergo activation in response to fibrogenic stimuli or tissue injury and play a central role in pancreatic fibrosis and tissue restitution [69–71]. PSCs are perivascular [72] and derived from vitamin A-containing cells that can acquire a myofibroblast phenotype [69,73]. These cells may be activated by transforming growth factor-β1 (TGB-β1), basic fibroblast growth factor and fibrogenic cytokines (e.g., TGF-β1, tumor necrosis factor-α, and interleukins 1 and 6) [69,74]. Furthermore, ethanol and the oxidative metabolite acetaldehyde (and oxidative stress) may directly activate PSCs [74], and the nonoxidative ethanol metabolites, the fatty acid ethyl esters, inhibit degradation of the extracellular matrix [75]. Activated PSCs secrete extracellular matrix proteins leading to tissue restitution or fibrosis depending on whether the duration of signaling by profibrotic growth factors and cytokines is a self-limited process (e.g., following an acute injury) or a perpetual process [71,76].

Intracellular or paracrine signaling pathways may be potential therapeutic targets to inhibit pancreatic fibrogenesis. General strategies directed towards PSCs may include inhibiting/inactivating PSCs, eliminating PSCs by inducing apoptosis [77] – which is an important step in wound healing [78] – or providing PSCs that have a restitutive phenotype with the ability to phagocytose inflammatory cells and reduce inflammation [79]. Major proteins of therapeutic interest as targets are the mitogenic peptides TGF-α and TGF-β, which are involved in cellular proliferation and differentiation. The central fibrogenic role for TGF-β was illustrated by showing that conditional loss of TGF-β signaling in mouse pancreas prevents fibrogenesis [80]. Furthermore, transgenic mice that overexpress TGF-α develop interstitial pancreatic fibrosis. Human studies demonstrated high levels of TGF-α and its messenger RNA in pancreatic tissue from patients with chronic pancreatitis, coupled with high levels of epidermal growth factor receptor [81], the receptor through which TGF-α acts. Another study [82] demonstrated overexpression of acidic and basic fibroblast growth factors in tissue from patients with chronic pancreatitis. Paracrine signaling loops between immune cells and PSCs likely perpetuate inflammation and PSC stimulation, as demonstrated by the finding that PSCs inhibit lymphocyte apoptosis by secreting interleukin-15 and in turn lymphocytes secrete PSC-activating inflammatory cytokines [83]. Although these observations are intriguing, it remains to be determined whether these abnormalities are contributing to the progression of disease or are merely a result of the disease process.

Cigarette smoking

An increasing number of studies indicate that cigarette smoking increases the risk and accelerates the progression of pancreatitis. Specifically, cigarette smoking increases the risk of developing acute [84,85] and chronic [84–88] alcoholic pancreatitis, and idiopathic chronic pancreatitis [85]. Lin and associates [88] reported that the odds ratio (95% confidence intervals) for chronic pancreatitis for smokers compared with nonsmokers, after adjustment for body mass index, education level, and alcohol consumption, was 7.8 (2.2–27.3) for all smokers, and greater risk was observed for those who had smoked for 25 years or more. The risk for chronic pancreatitis significantly increased with increasing cumulative amount of smoking. Other studies showed that cigarette smoking increases the risk for pancreatic calcification of late-onset but not of early-onset idiopathic chronic pancreatitis [89]. Furthermore, smoking is associated with earlier onset of alcoholic chronic pancreatitis [87] and accelerated progression of both alcoholic chronic pancreatitis [86] and late-onset, but not early-onset, idiopathic chronic pancreatitis [90]. An important interaction among calcification, smoking, and alcohol ingestion is that calcifications occurred more frequently in smokers and correlated with the amount and duration of drinking [20,91,92].

Based on these and other studies, the role of smoking in the causation of chronic pancreatitis in the absence of alcoholism is strongly suspected but not conclusively proved. However, it appears that smoking enhances the progression of chronic pancreatitis, especially of calcification. In hereditary pancreatitis, smoking increases the risk for pancreatic cancer and lowers the age at onset by about 20 years [93]. Finally, exposure to cigarette smoking and, probably, alcohol consumption contribute to cardiovascular disease, which is the leading cause of death in patients with alcoholic chronic pancreatitis [25]. Hence, patients with chronic pancreatitis, regardless of the cause, should stop smoking.

Tropical (nutritional) pancreatitis

Tropical chronic pancreatitis, one of the major nutritional forms of chronic pancreatitis, is an important disease among juveniles and young adults in some African and Asian countries (Indonesia, southern India, and tropical Africa) [94,95]. The natural history of tropical chronic pancreatitis is succinctly summarized by Gee Varghese [95] as "recurrent abdominal pain in childhood, diabetes around puberty, and death at the prime of life." Abdominal pain characterizes the onset of tropical pancreatitis. The onset of diabetes typically

occurs a few years after the onset of abdominal pain. Diabetes is characteristically brittle, with marked fluctuations of blood glucose. At this time, abdominal radiographs invariably show diffuse pancreatic calculi. Microscopically, dilation of the ducts, pancreatic lithiasis, chronic inflammatory cell infiltration, and atrophy of the pancreatic parenchyma are seen.

The etiology of tropical pancreatitis is not clearly understood, but appears to be associated with both nutritional and genetic risk factors. In most the common denominator appears to be malnutrition [96]. Evidence suggests that other factors, such as toxic products in certain nutritional components (cassava), may be more important [97]. Cassava is consumed in large quantities by most poor people in many African and Asian countries. It contains 65 mg of toxic glycoside per 100 g. When glycosides react with gastric hydrochloric acid, hydrocyanic acid is liberated. The enzyme rhodanase acts on hydrocyanic acid, leading to thiocyanate production in the presence of adequate amounts of methionine and cysteine. Cyanogens impair a number of enzymes, including superoxide dismutase, an important scavenger of free radicals, which are proposed to cause cell injury [98,99]. Associated nutritional deficiencies, such as deficiencies of zinc, copper, and selenium, which are common in malnutrition, interfere with the detoxification of cyanogens. Thus, the pathogenesis of tropical pancreatitis may be partly explained by micronutrient and antioxidant deficiencies and by unopposed free radical injury secondary to dietary cyanogens.

Investigation of risk factors other than dietary elements is relevant for understanding the pathobiological mechanisms of tropical pancreatitis because the disease also occurs independently of cassava consumption and in people without suspicion of malnutrition. Variable familial clustering of the disease further raised suspicions of a genetic defect. Previous studies showed no association of tropical pancreatitis with gene mutations for *CFTR* [100], *reg1A101*, or *PRSS1* [102,103]. However, multiple concurrent investigations led to the detection of the serine protease inhibitor, Kazal type 1 (*SPINK1*) gene mutation at residue N34S in 20%–55% of patients with tropical pancreatitis [104–109], compared to 10%–14% in early-onset type II (non-insulin-dependent) diabetes mellitus [106,109], and 1.3%–5.6% in control subjects [106–109]. Conceptually, mutations in the *SPINK1* gene impair the normal functioning of trypsin inhibitor, a safety mechanism for preventing pancreatitis by inhibiting activated trypsin within acinar cells. However, unlike in hereditary pancreatitis (discussed below), most clinical studies support the idea that the *SPINK1* missense mutation in codon N34S is a disease modifier rather than a cause of pancreatitis [110] because the prevalence of N34S *SPINK1* gene mutations (~ 2%) is far greater than the prevalence of chronic pancreatitis (0.006%) [110] and the pancreatitis phenotype is no different with either homozygous or heterozygous N34S *SPINK1* gene mutations [107,111]. Hence additive risk arising from multiple rather than single factors is likely responsible for tropical pancreatitis, including dietary, genetic, and, perhaps, other risk factors.

Hereditary pancreatitis

The clinical picture of hereditary pancreatitis was well described in 1952 by Comfort and Steinberg [112]. Since then, many similar cases have been reported, primarily in Caucasians from different areas of the world (United States, Ireland, France, and New Zealand), but also in some Japanese families [113]. It is an autosomal dominant disorder with 80%–96% penetrance and variable expression that begins in childhood [114,115]. The incidence is about equal in both sexes [116]. Between 52% and 81% of patients with hereditary pancreatitis have mutations in the gene for cationic trypsinogen (*PRSS1*) [114,115,117]. LeBodic and colleagues [118] from France, and Whitcomb and associates [119] from the United States, mapped the gene to the long arm of chromosome 7 (7q55). Subsequently, by positional cloning, Whitcomb and colleagues [117,120] identified two genetic mutations in the cationic trypsinogen gene in hereditary pancreatitis – a missense mutation R117H on exon 3117 and a mutation in exon 2 of the gene (N21I) [120] – in relatives without the R117H mutation. It was hypothesized that cleavage at these sites of the trypsinogen molecule is part of a failsafe mechanism to inactivate trypsin within the pancreas. Gene mutations result in failure of cleavage and persistent tryptic activity, causing autodigestion of the pancreas and pancreatitis. These mutations have since been described in families with pancreatitis around the world [121–125]. They represent the causative mutation in about two-thirds of the families with classic hereditary pancreatitis and are the only mutations for which genetic testing is recommended.

In addition to the typical hereditary form described by Comfort and Steinberg, which begins at a young age, familial aggregations of two or three cases, with attacks beginning in the third or fourth decade [126], have been reported. This suggests that there may be different forms of hereditary transmission. Mutations at codons 16 [127], 22 [128], and 23 [123] in the trypsinogen gene, although significantly associated with chronic pancreatitis, have a low penetrance. These mutations may be present in patients with a diagnosis of sporadic idiopathic pancreatitis. However, trypsinogen gene mutations are not the cause of tropical pancreatitis, even if many family members are affected [102].

The clinical picture of hereditary pancreatitis differs little from that of nonhereditary pancreatitis [116] and carries a high risk for pancreatic cancer [129]. Patients frequently experience recurrent attacks of severe upper abdominal pain. Overt diabetes develops 8–10 years after the onset of pain in 20% of cases, and gross steatorrhea in 15%–20%. The diagnosis of hereditary pancreatitis should be suspected if two or more family members have pancreatitis in the absence of alcohol consumption or other causes of chronic pancreatitis. This criterion may be too stringent [113] based

on reports of "sporadic" cases of hereditary pancreatitis [113,123,127,128,130] and because up to 11% of mutation-positive individuals may be silent carriers [115]. Indeed, variances in the application of diagnostic criteria to clinical studies will influence a study's outcome. For example, in a European cohort of 112 hereditary pancreatitis families identified by these "strict" criteria [114], 81% had mutations of R122H, N29I, or A16V, compared to 51% reported previously [115] and 96% had disease penetrance, compared to 80% [115]. Similar findings in the two studies are the life-time pancreatic cancer risk of 44% [114] compared with 40% [115]. Moreover, cigarette smoking accelerates the onset of pancreatic cancer, which occurs 14 years earlier in smokers than innonsmokers [131]. Genotype/phenotype analyses indicate that individuals with the more common R122H mutation presented 4–5 years earlier than persons with a mutation in N29I or with no identifiable mutations [114] and were more frequently hospitalized than the N29I mutation patients [114]. Conversely, patients with N29I mutations were treated at an earlier age with pancreatic resection for pain [114]. Hence, in contrast to a previous report [120], the data are conflicting on whether the R122H mutation increases the risk for more aggressive disease [114,120]. As a result of the high disease penetrance and markedly increased life-time risk of pancreatic cancer, current guidelines favor genetic screening for *PRSS1* gene mutations when hereditary pancreatitis is suspected [132].

Hyperparathyroidism

Calcified chronic pancreatitis occurs in untreated hyperparathyroidism. Surveys suggest that the incidence is decreasing and is no greater than 1%–2% [133]. A likely explanation is that serum calcium is measured routinely in virtually all patients who undergo a medical checkup, and, as a result, hyperparathyroidism does not remain undiscovered and untreated for many years. The pathogenesis of pancreatitis in hyperparathyroidism is presumed to be related to the effect of hypercalcemia. Acute hypercalcemia is a potent stimulus of human pancreatic enzyme secretion [134,135]. Furthermore, chronic hypercalcemia causes a significant increase in pancreatic calcium secretion in patients with hyperparathyroidism and in experimental animals. This results in precipitation of intraductal calcium in pancreatic juices. Moreover, chronic hypercalcemia causes a decrease in the diffusion barrier between the pancreatic interstitial compartment and the ductal system, resulting in excessive diffusion of calcium ions into the pancreatic juices. These events may damage the pancreas and promote the development of calcified chronic pancreatitis.

Hyperlipidemia

As discussed in Chapter 68, it is well known that hyperlipidemia can cause acute pancreatitis. After repeated episodes of acute pancreatitis, hyperlipidemia may, on rare occasions, cause chronic pancreatitis. It is important to consider this unusual cause because effective therapy is available. Glueck and associates [136] highlighted the risk for estrogen replacement in postmenopausal women with underlying hypertriglyceridemia. Twelve women receiving estrogen replacement were studied; 10 of these had fasting triglycerides greater than 1200 mg/dL while receiving estrogens, and six developed pancreatitis. Stopping estrogen replacement therapy and treatment of the underlying hypertriglyceridemia returned triglycerides to normal levels. Fasting triglyceride levels of less than 300 mg/dL pose no risk for estrogen-induced pancreatitis, whereas levels greater than 750 mg/dL are associated with a high risk. Therefore, it is important to measure fasting serum triglycerides before initiating estrogen replacement therapy in postmenopausal women to prevent acute pancreatitis and avoid the potential for chronic pancreatitis.

Autoimmune pancreatitis

Chronic pancreatitis may be caused by autoimmunity [137]. The prevalence of autoimmune pancreatitis is reported as 2%–8% in non-US populations [138,139]. Data from the United States indicate that autoimmune pancreatitis is mistaken for pancreatic cancer and is diagnosed at surgery in 2.5% of cases [138]. The number of publications per year on autoimmune pancreatitis increased exponentially in the last 6 years, reaching nearly 100 publications in 2006. Many of the first case series were reported in the Japanese literature followed by a multitude of publications from other countries leading to identification of different features or subsets of the disease (see Table 69.3) and to the generation of two sets of diagnostic criteria: the Mayo Clinic [140] HISORIt criteria (Histology, Imaging, Serology, Other organ involvement, Response to steroid therapy) and the revised Japanese Pancreas Society criteria [141]. Autoimmune pancreatitis typically affects the elderly (mean age 63–68 years) [140,142],

Table 69.3 Geographic variation in the clinical presentation of autoimmune pancreatitis

Clinical presentation	Mayo experience	Japanese experience
Jaundice (painless)	73%	86%
Abdominal pain (mild)	34%	
Mass	10%	
New-onset diabetes	~ 3%	41%
Steatorrhea	~ 3%	Uncommon
Pancreatitis	~ 3%	
Calcifications	Uncommon, ~ 50% of relapses	Uncommon, 50% of relapses

Data collected from Chari et al. [140] (Mayo Clinic) and from Takayama et al. [139], Kamisawa et al. [142] and Horiuchi et al. [143] (Japanese publications).

men (> 80% predominance) [140,142], and presents as painless jaundice (73%–86%) [139,140,142,143] followed by mild abdominal pain (34%) [140] or the appearance of a pancreatic mass lesion (10%) [140]. Uncommon initial presentations [139,140,142,143] include pancreatitis, steatorrhoea, and calcification. New-onset diabetes mellitus is reported to be rare in the Mayo Clinic series [140] but is common (41%) in the Japanese literature [139,142,143]. The major clinical presentation, obstructive jaundice, is caused by stenosis of the common bile duct, which is otherwise rare in other types of pancreatitis [144]. Steroid therapy is usually effective in alleviating the stenosis of the common bile duct as well as that of the pancreatic duct [145,146], providing a provocative example of a potentially reversible type of chronic pancreatitis.

Not only pancreatic core biopsy but also imaging studies, laboratory data, and, potentially, genetic profiling provide useful information for diagnosing autoimmune pancreatitis. In Japan, computed tomography (CT) and ultrasonography usually show a diffusely enlarged pancreas, with a sausage-like appearance and a capsule-like rim that is of low density on CT [141]. Initially, pancreatic calcification or pseudocyst is seldom observed, but calcifications occur in around 50% of patients who relapse following prednisone therapy [143]. Endoscopic retrograde cholangiopancreatography (ERCP) usually shows segmental or diffuse narrowing of the main pancreatic duct and extrinsic stenosis of the intrapancreatic portion of the common bile duct, resulting in dilation of the proximal biliary tract. The differential diagnosis of diffuse pancreatic enlargement includes malignant lymphoma, plasmacytoma, metastasis, and diffuse infiltrative pancreatic carcinoma. Definitive diagnosis by the Japanese criteria requires diffuse pancreatic enlargement and diffuse or segmental pancreatic duct narrowing plus either abnormal serological tests (described below) or suggestive histopathology [141]. In contrast, based on prospectively collected data from 59 patients at the Mayo Clinic, the HISORIt criteria (see Table 69.4) are less rigid and allow for the diagnosis to be made in one of three ways:

- histology
- imaging and serology
- serology, other organ involvement and response to steroid therapy [140].

Diagnostic histological findings most commonly show fibrotic changes with infiltration of lymphocytes and plasma cells and, sometimes, eosinophils around the pancreatic duct associated with obliterative phlebitis, cholangitis, and edema, labeled as lymphoplasmacytic sclerosing pancreatitis [147]. The lymphocytes are usually CD4+ and human leukocyte antigen (HLA) DR+ T cells [148–150]. The HLA-DR is also expressed on pancreatic duct cells [148,151]. A less common histological variant found in younger patients shows neutrophil predominant lobular inflammation without phlebitis, termed idiopathic duct centric chronic pancreatitis [152]. When pancreatic tissue specimens are not available, laboratory data and clinical history provide useful information that may increase the suspicion of autoimmune pancreatitis. Patients frequently have circulating autoantibodies (e.g., antinuclear antibody, antilactoferrin antibody, anticarbonic anydrase II antibody, rheumatoid factor, anti-smooth muscle antibody) and may have another autoimmune disease (Sjögren disease, primary sclerosing cholangitis, ulcerative colitis, systemic lupus erythematosus, primary biliary cirrhosis) [153]. A recent, inclusive characterization of the disease is that autoimmune pancreatitis is one manifestation of an immunoglobulin G4 (IgG4)-related autoimmune disease [138], because increased serum β-globulin or IgG4 levels are common and IgG4 deposition may be detected in a variety of tissues [138]. Reported IgG4 organ involvement includes sclerosing sialadenitis, sclerosing cholangitis, sclerosing cholecystitis, retroperitoneal fibrosis, joint involvement in patients with rheumatoid arthritis and amyloidosis, gastrointestinal tract mucosal deposition, bone marrow involvement in myelodysplastic syndrome, inflammatory pseudotumors of the spleen, lung and liver, lymphadenopathy, tubulointerstitial nephritis, and interstitial pneumonia [154–164]. A genetic basis of autoimmune pancreatitis is under investigation and indicates that up to 33% of patients have *SPINK1*

Table 69.4 Diagnosis of autoimmune pancreatitis by the Mayo Clinic HISORIt Criteria: one of three combinations of data are diagnostic

	H	I	S	O	Rt
	Histology	**Imaging (CT):**	**Serology elevated serum IgG4**	**Other organ involvement**	**Response to steroids therapy**
Group A: (n = 29)	X				
Group B: (n = 3)		X	X		
Group C: (n = 17)			X or X		X

gene mutations [43], which are associated also with idiopathic and tropical pancreatitis, and some patients have a DRB1*0405-DBQ*0401 haplotype [165]. The large number of epidemiological, histopathological, and genetic studies on autoimmune pancreatitis have provided further understanding of subgroups of patients who were formerly classified as having late-onset but also early-onset idiopathic chronic pancreatitis [166].

Obstruction

Obstruction of the main pancreatic duct by tumors, benign vaterian stenosis [167], scars (e.g., from traumatic pancreatitis), and pseudocysts [168] can lead to a distinct form of chronic pancreatitis known as *obstructive chronic pancreatitis*. This is characterized by acinar atrophy and fibrosis and dilation of the ductal system. In contrast to alcohol-induced chronic pancreatitis, intraductal plugs or stones are very rare in obstructive chronic pancreatitis, and both structural and functional changes may improve when the obstruction is relieved [167]. The regression of fibrotic lesions may be explained by the finding that fibrosis in experimental obstructive pancreatitis consists of fractions of collagen with short half-lives (fibronectin, laminin, collagen III, and procollagen III) rather than the long-lived fraction collagen I [169].

Trauma

Trauma to the abdomen or back may be clinically insignificant and still produce significant pancreatic injury, leading to chronic pancreatitis. The pathogenesis may follow that of the obstructive type, but inflammation and pseudocysts frequently develop. Recognition of trauma as the cause for chronic pancreatitis is important because most cases are associated with severe ductal disruption, which responds poorly to medical treatment, but the results of surgical correction (particularly partial pancreatectomy) have been excellent [170,171].

Idiopathic chronic pancreatitis

The major form of nonalcoholic chronic pancreatitis in North America and Europe is the idiopathic type (10%–40%). Epidemiological and clinical studies suggest that idiopathic chronic pancreatitis may be divided into two distinct groups: a juvenile type, with onset of symptomatic disease at a median age of 18 years; and a senile type, with an incidence peak at 60 years of age. In juvenile chronic pancreatitis, abdominal pain dominates the clinical picture at initial presentation, whereas in senile groups, painless disease is frequent, and most patients present with exocrine insufficiency, diabetes, and pancreatic calcification [172].

Landmark genetic studies indicate that *CFTR* gene mutations are linked to some patients with chronic pancreatitis. Sharer and colleagues [46] searched for 22 *CFTR* mutations in 134 patients who had idiopathic chronic pancreatitis or chronic pancreatitis as the result of alcoholism, hyperparathyroidism, or hypertriglyceridemia. In these patients, *CFTR* mutations were seen at 2.5 times the expected frequency, and the frequency of the 5T allele (which is associated with a reduced proportion of functional *CFTR*) was twice the expected frequency. In a separate study, Cohn and associates [173] found that 10 of 27 patients with idiopathic chronic pancreatitis had at least one of 17 *CFTR* mutations; both alleles were affected in three patients. The 5T allele was present in 5 of 27 patients; this was twice the expected frequency. Hence, it is intriguing that at least a subset of patients who would be classified as having idiopathic chronic pancreatitis has *CFTR* mutations. Subsequent genetic studies show that the true prevalence of *CFTR* mutations is approximately 50% in idiopathic pancreatitis compared with 22% in controls when exhaustive gene identification methods are performed [174]. Genetic studies also provide evidence of mutations other than *CFTR* in early-onset idiopathic chronic pancreatitis; around 50% of patients formerly classed as having early-onset idiopathic chronic pancreatitis have *SPINK1* [41,43,175–177] (see section on tropical pancreatitis) or *CFTR* [46,173,176,178] gene mutations. The functional significance and clinical relevance of these mutations on the pancreas are unclear, but most patients in the above studies did not have classic cystic fibrosis. They all had normal sweat chloride test results and nasal potential difference. Cohn and associates, in a review, stated, "at present, the role of *CFTR* mutation testing in idiopathic chronic pancreatitis is uncertain because no guidelines exist for genetic counseling or altered clinical management of idiopathic chronic pancreatitis based on the results of such testing," [179].

Pancreas divisum

Pancreas divisum is the most common congenital abnormality of the pancreas, comprising in 4%–24% [180]. Fusion of the dorsal and ventral pancreatic ducts is absent or incomplete, and drainage of the major portion of the pancreas occurs through the minor papilla (see Chapter 67). The clinical significance of pancreas divisum is unknown, although considerable controversy surrounds this issue [180].

A central point of contention is whether the incidence of idiopathic pancreatitis, particularly idiopathic recurrent acute pancreatitis, is increased in subjects with pancreas divisum, a question raised almost exclusively by endoscopic studies. Earlier endoscopic studies by Cotton [181], Sahel [182], and Richter [183] and their colleagues indicated that the prevalence of pancreas divisum was increased in idiopathic pancreatitis but this was contradicted by later studies by Burtin [184], Delhaye [185], and Sugawa [186] and their associates. To explain the differences between these two groups of studies, it is possible that the results from the earlier studies [181–183] might be biased by patient selection and that the patients had poorly characterized pancreatic diseases. Authors use different terminology for pancreatitis and likely enter different subsets of patients into their studies.

Finally, patients with pancreas divisum and patients with idiopathic pancreatitis are likely to be referred to centers with exceptional endoscopic skills, and, as a result, the incidence of pancreas divisum may appear to be increased, whereas such an increase is not present in a more random sampling of patients.

The prevalence of pancreas divisum in idiopathic pancreatitis and the general population was clarified by a comprehensive bi-part analysis of data published as a clinical controversy topic [180]. Prevalence data for pancreatitis in pancreas divisum was determined for 28 803 patients from 77 studies – 23 autopsies [187–209], 41 ERCP studies [181–186,209–243], and 13 magnetic resonance cholangiopancreatography (MRCP) studies [235,244–255] – and categorized according to the following terms: no pancreatitis, idiopathic pancreatitis, and acute pancreatitis and chronic pancreatitis when sufficient detail supported this designation [180]. Whereas autopsy and MRCP studies provide overwhelming evidence that the prevalence of pancreas divisum in the general population is around 8%, ERCP studies report a prevalence of approximately 4% for pancreas divisum in patients idiopathic pancreatitis (general population) and about 8% prevalence in patients with idiopathic pancreatitis (see Fig. 69.1). Hence, there does not appear to be an association between pancreas divisum and idiopathic pancreatitis and the increased frequency of pancreas divisum reported in some endoscopic studies is likely attributable to underrecognition of pancreas divisum in the general population or referral bias.

Many patients with idiopathic pancreatitis and pancreas divisum are commonly mislabeled as having idiopathic recurrent acute pancreatitis. The data from Choudari and colleagues [256] indicate that in patients with idiopathic pancreatitis and pancreas divisum, predisposing factors (e.g., *CFTR* gene mutations) other than pancreas divisum are necessary for pancreatitis to develop [46]. It has been hypothesized that the opening of the lesser papilla might be too small to permit the free flow of pancreatic juice into the duodenum, and, as a result, pancreas divisum might cause a form of obstructive pancreatitis. Indeed, the results of an uncontrolled surgical study showed that reduction in pancreatic duct and sphincter pressures following sphincteroplasty predicted a good outcome [257]. These findings should be interpreted cautiously because as was pointed out, "... diagnostic tests for assessing the presence of functional obstruction are not specific (secretin induced duct dilatation detected by ultrasound/MRCP is 'abnormal' in 50% of normal controls

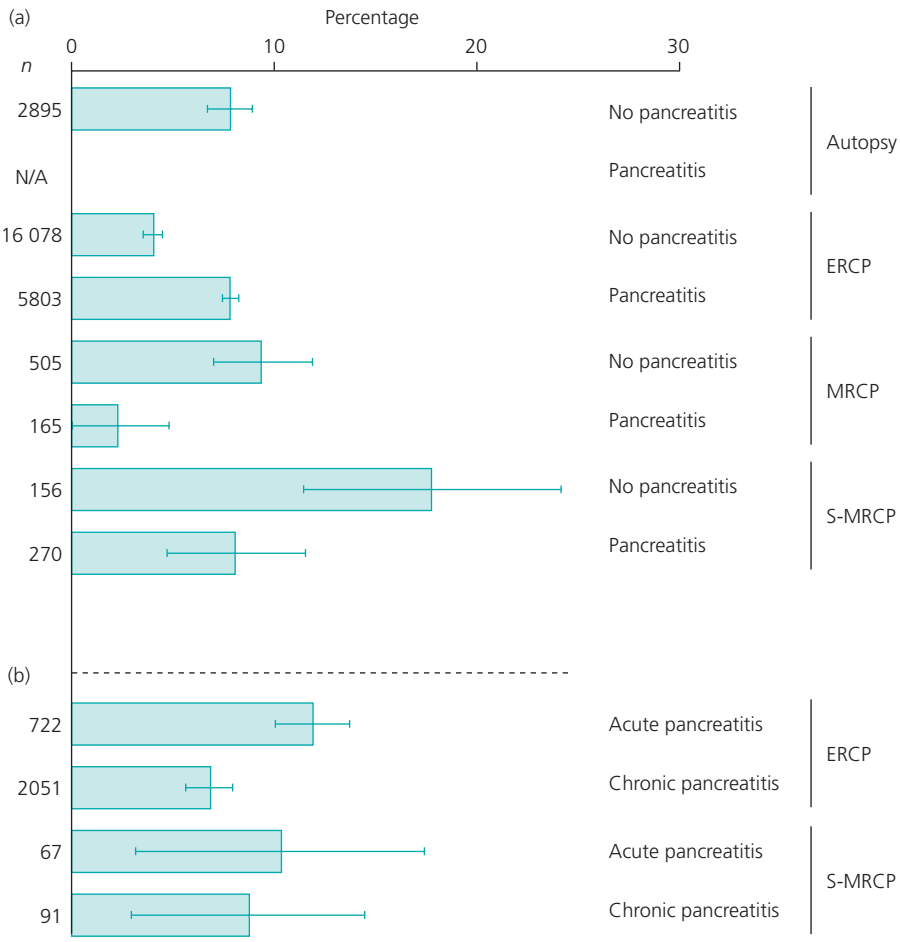

Figure 69.1 Prevalence of pancreas divisum. Bars represent mean pancreas divisum as % total cases (*n*) and error bars are 95% confidence intervals. Panel **3(a)** is the prevalence of pancreas divisum without or with pancreatitis reported in autopsy, endoscopic retrograde cholangiopancreatography (ERCP) and secretin-magnetic resonance cholangiopancreatography (S-MRCP) studies. [180], with permission from Lippincott Williams and Wilkins.

[258] and does not differ in patients with or without pancreas divisum [249,250]), or results of standardized tests (sphincter manometry) do not correlate with symptoms or predict response to intervention [180,259]."

Gelrud and colleagues [260] further illustrated that endoscopic therapy has unclear effectiveness for treating pain in those with idiopathic pancreatitis, pancreas divisum and CFTR dysfunction. Gelrud and colleagues [260] substantiated the clinical association of aberrant CFTR function with idiopathic pancreatitis and pancreas divisum and reported that only 2 of 12 patients had resolution of symptoms even though all had 2–5 ERCPs, 10 of the 12 had endotherapy (stent/sphincterotomy), and 8 of the 12 had a cholecystectomy. Although the therapeutic component of this study was not randomized or controlled, the results do not endorse invasive therapy.

Clinical presentation

Pain

The presenting symptom of most patients with chronic pancreatitis is abdominal pain. The pain is usually epigastric, dull rather than sharp, and constant rather than colicky. Although the pain may radiate to both upper quadrants and, occasionally, to the lower quadrants, a characteristic feature is radiation directly through to the back. The pain is partially relieved by sitting with the trunk bent forward or lying prone; the supine posture aggravates the discomfort. The almost instantaneous aggravation of pain by food ingestion is characteristic of chronic pancreatitis or carcinoma of the pancreas, and this symptom should always raise the suspicion of pancreatic disease. Although food ingestion may aggravate the pain of other abdominal conditions (i.e., irritable bowel syndrome), there is usually a much greater interval between the meal and the discomfort than is the case with pancreatic disease. Ingestion of alcohol may also aggravate the pain, although a sizable fraction of patients claim that the pain develops after 12–24 h of abstinence [261].

Pain patterns may differ depending on the type of chronic pancreatitis [25]. At the beginning of disease, pain is present in 75% of patients with alcoholic chronic pancreatitis, 50% of patients with late-onset idiopathic chronic pancreatitis, and nearly all patients with early-onset idiopathic chronic pancreatitis. Pain tends to be less severe in the late-onset idiopathic group.

A prospective longitudinal study of alcoholic chronic pancreatitis identified two major patterns of pain. Ammann and Muellhaupt [262] reported that 44% of the patients had short episodes of pain, type A pain – defined as short episodes of usually less than 10 days' duration, separated by long pain-free intervals of months to years. The patients with mild to moderate chronic pancreatitis rarely had constant pain, so none of these patients underwent surgery for pain relief. By contrast, 56% of patients had episodes of constant daily pain, type B pain – defined as occurring on 2 or more days per week for at least 2 months. Importantly, most patients with constant (type B) pain had local complications such as pancreatic pseudocysts or obstructive cholestasis that were amenable to surgical correction. It is important to emphasize that the above study only evaluated alcoholic chronic pancreatitis patients who were not addicted to narcotics. Therefore, these findings are not applicable to patients who are addicted to narcotics and who have any form of chronic pancreatitis.

To address the limitations of the above study, a long-term natural history study described pain patterns that are common or unique to alcoholic and non-alcoholic chronic pancreatitis [90] based on a mixed cohort of patients. Ammann's group [90] emphasized that the natural history of chronic pancreatitis differs among etiologies. They corroborated and extended the data from a previous study [25], by reporting a "significantly delayed progression of exocrine insufficiency and calcification from onset in IJCP (juvenile or early-onset idiopathic chronic pancreatitis)/HP (hereditary pancreatitis) compared to alcoholic chronic pancreatitis (alcoholic)/ISCP (senile or late-onset idiopathic chronic pancreatitis)." A major finding was that type A pain (see above) was the predominant pain pattern in senile idiopathic chronic pancreatitis and hereditary pancreatitis and was managed without invasive procedures (surgery). Type B pain (see above) occurred in approximately 60% of alcoholic chronic pancreatitis and juvenile idiopathic chronic pancreatitis, was predominantly associated with local complications, and required surgery. These data have important negative implications for invasive therapies in chronic pancreatitis patients without local complications.

Pain in chronic pancreatitis may continue, diminish, or disappear completely. Several reports have suggested that pain may disappear as the severity of pancreatitis increases [25,53,263–265]. According to Ammann [265], pain disappears coincident with the appearance of calcifications, steatorrhea, and diabetes, which occurs 5–8 years after the onset of chronic pancreatitis. With different etiologies for chronic pancreatitis, the disappearance of pain occurs at a similar frequency but over variable time spans; pain decreased/disappeared in early-onset idiopathic chronic pancreatitis, late-onset idiopathic chronic pancreatitis, and alcoholic chronic pancreatitis in 67%, 64%, and 77% of patients over a mean duration of 27 ± 3, 13 ± 2, and 14 ± 1 years, respectively [25]. Chronic pancreatitis is painless or relatively painless (i.e., insufficient pain to require medical evaluation) in about 15% of patients [266]. Idiopathic pancreatitis is more likely to be painless than the alcoholic variety. Most studies report that pain diminishes/disappears over time, and at least one study reported that the frequency of pain relief was similar in those who had or did not have surgery [25,267] so the recommendation for offering invasive therapies to patients with chronic pancreatitis, particularly type A pain,

should be carefully weighed against the natural history of pain in this disease.

Weight loss

Nausea, vomiting, anorexia, and weight loss are common in chronic pancreatitis. The major cause of weight loss is decreased caloric intake owing to fear of aggravation of the abdominal pain, although malabsorption or uncontrolled diabetes may also play a role. Marked weight loss is relatively unusual in other painful abdominal conditions, such as peptic ulcer or irritable bowel syndrome, and the combination of chronic upper abdominal pain and rapid loss of weight should always suggest the possibility of pancreatic disease.

Malabsorption

Diarrhea, steatorrhea, and azotorrhea occur when exocrine secretion of pancreatic enzymes is insufficient to maintain normal digestion. Although most attention has been directed to the malabsorption of fat and protein in this condition, studies using hydrogen breath tests have also demonstrated malabsorption of starch [268].

Malabsorption does not occur until enzyme secretion is reduced to less than 10% of normal [269,270] so diarrhea and steatorrhea occur relatively late in the course of chronic pancreatitis. As a rule, fecal weight is less in pancreatic malabsorption than in other conditions with comparable steatorrhea. This relatively low fecal weight reflects less fecal water, and patients may pass bulky, formed stool, as opposed to the frank watery diarrhea observed in other conditions. The relatively low fecal water in pancreatic insufficiency probably results from the better absorption of some carbohydrates, such as disaccharides, that occurs in conditions with mucosal pathology, such as celiac sprue. Occasionally, the patient observes that gross oil leaks from the rectum or floats as an "oil slick" on the surface of the water in the toilet bowel. If ingestion of mineral oil is excluded, this finding is usually indicative of pancreatic steatorrhea. For a given degree of steatorrhea, the absorption of fat-soluble vitamins (A, D, E, and K) is much better in pancreatic insufficiency than in celiac sprue [271]. Marked deficiency of these vitamins is seldom observed in pancreatic insufficiency, and presumably this reflects the relative unimportance of lipolysis for the absorption of these compounds. The body stores of these vitamins, however, have been shown to be reduced in a large fraction of patients with chronic pancreatitis, although clinical manifestations of the deficiencies are rare [272].

Pancreatic diabetes

Glucose intolerance is common early in the course of chronic pancreatitis. Data are limited but in patients with mild to moderate alcoholic chronic pancreatitis an abnormal oral glucose tolerance test was present in 68% and hyperglycemia was found in 32% [273]. Clinically evident diabetes may be an initial manifestation of asymptomatic chronic pancreatitis [274], an observation known to clinicians, particularly in South Africa and India, but it more commonly occurs relatively late in the disease. Endocrine insufficiency eventually occurs in most patients with chronic pancreatitis. In a follow-up study of 500 patients with chronic pancreatitis, of whom 85% were alcoholic, it was reported that diabetes developed in 83% within 25 years after the clinical onset of chronic pancreatitis, and more than half required insulin treatment [275]. The prevalence of diabetes was similar in patients who underwent surgery and those who received medical treatment. However, for those who had pancreatic surgery, the prevalence of diabetes was significantly higher 5 years after distal pancreatectomy (57%) than after pancreaticoduodenectomy, pancreatic drainage, or cystic drainage (24%–36%). Pancreatic drainage did not prevent the onset of diabetes. Distal pancreatectomy and early onset of pancreatic calcifications were the only independent risk factors for diabetes.

Ketoacidosis and diabetic nephropathy are relatively uncommon in pancreatic diabetes. For a given duration of diabetes, however, retinopathy and neuropathy are thought to occur with a frequency similar to that in idiopathic diabetes mellitus [276].

Other clinical features

Other clinical presentations of chronic pancreatitis include jaundice, secondary to common bile duct compression by the pancreas; ascites or pleural effusion, caused by leak of pancreatic secretions from a ruptured duct or pseudocyst; painful nodules, usually over the lower extremities, resulting from fat necrosis; and, rarely, a polyarthritis of the small joints of the hands. In the United States, at least 70% of chronic pancreatitis is attributed to prolonged, heavy ingestion of ethanol, whereas the bulk of the remaining 30% is idiopathic. Historical information concerning length and duration of ethanol ingestion is therefore critical in all suspected cases of chronic pancreatitis. In contrast, gallstone disease is almost never the cause of chronic pancreatitis. A family history of pancreatitis or chronic abdominal pain of unknown origin may suggest the diagnosis of familial pancreatitis.

Physical examination is usually of limited assistance in the diagnosis of chronic pancreatitis. There is epigastric tenderness during the painful episodes (and sometimes during periods of remission). Tenderness ranges from mild to marked, but involuntary guarding and rebound are unusual. The physical signs characteristically are trivial relative to the intensity of the patient's complaints. Complications of chronic pancreatitis, such as pseudocysts, ascites, or pleural effusions, may be detected on physical examination.

Pathomechanism of symptoms

Abdominal pain and malabsorption are the major symptoms of chronic pancreatitis. The pathophysiological processes

responsible for the development of these symptoms are discussed in the following sections.

Pain

The mechanisms of pain in chronic pancreatitis are unclear. Possible causes include inflammation of the pancreas, increased intrapancreatic pressure, microvascular ischemia, neural inflammation, and extrapancreatic causes, such as common bile duct stenosis, duodenal stenosis, and pseudocysts.

Acute inflammation of the pancreas, during a relapsing attack of chronic pancreatitis or peripancreatic inflammation involving the duodenum and retroperitoneum, may cause pain. This may be mediated by inflammation or fibrosis. Cytokines such as interleukin-6 and interleukin-8 [277] and chemokines such as Mob-1 and tumor necrosis factor-α may be involved in inflammatory and fibrosis pathways. Whether fibrosis by itself produces pain is unclear, but in chronic pancreatitis the link between fibrosis and pain is probably related to pancreatic stellate cells, which are responsible for pancreatic fibrosis [278]. With their contractile potential and their perivascular location, these cells could cause microvascular ischemia and pain [278] when stimulated by growth factors [69].

Clinical and experimental evidence suggests that pain may also be related to increased intraductal pressure secondary to continued pancreatic secretion in the face of ductal obstruction caused by strictures or intraductal stones [279]. The increased pancreatic ductal and parenchymal pressure may also produce a compartment syndrome that induces ischemia and pain. This thesis is supported by experimental studies that showed increased interstitial and perfusion pressures and decreased blood flow in feline chronic pancreatitis [280,281]. These abnormalities were significantly reversed by surgical incision of the gland and draining of the pancreatic duct [281].

Several clinical studies showed that pain relief correlates with the development of pancreatic insufficiency in patients with alcohol-induced chronic pancreatitis [115,116]. Measurements of intraductal pressure have been made in patients without pancreatic disease and in those with ductal abnormalities. Among patients without pancreatic disease, intraductal pressure has been found to be 7 mmHg by direct puncture at surgery in one patient and between 10 and 16 mmHg by ERCP among 33 patients without pancreatic disease [282–285]. By comparison, in 59 patients with a dilated duct, intraductal pressure measured by direct puncture at surgery ranged from 18 to 48 mmHg [285]. In one study [282], all 19 patients with a dilated main pancreatic duct with elevated intraductal pressure had prompt relief of pain after decompression surgery. Pancreatic tissue pressure also appears to be elevated among patients with chronic pancreatitis with a dilated pancreatic duct and those with pseudocyst [279,286]. The pancreatic tissue pressure normalized after decompression of the duct or cyst, and this resulted in pain relief in 12 of the 14 patients. Hence, these observations support the thesis that pain in chronic pancreatitis is related to increased intraductal and pancreatic tissue pressure. This provides the rationale for treatments that may reduce pancreatic secretion, such as octreotide, specific diets, and pancreatic enzyme therapy.

Intrapancreatic neural inflammation is another factor that may play an important role in the genesis of pain in chronic pancreatitis. Morphological studies indicate that pancreatic nerves appear to be larger and more numerous in chronic pancreatitis [287]. The organization of intraneural organelles, such as microtubules, is disrupted. Most significantly, however, there is an alteration in the perineural sheath that ordinarily shields nerves from surrounding connective tissue [287]. The damaged perineurium allows penetration of biologically active materials from the surrounding extracellular matrix, and pain may result from the continual stimulation of the sensory fibers by noxious substances. In this regard, immunohistological studies have shown that the amount of neurotransmitters, such as substance P and calcitonin gene-related peptide (CGRP), are increased in afferent pancreatic nerves in human chronic pancreatitis [288,289]. Immune cell infiltration and growth-associated protein 43 also correlate with pain intensity [290]. There is also evidence that eosinophils are increased in the perineural space among patients with recent alcohol consumption [291]. It is conceivable that degranulation of these eosinophils might be a factor in the generation of pain.

Capsaicin-sensitive afferent sensory neurons are considered a common final pathway in neurogenic pancreatic inflammation, including plasma extravasation, neutrophil infiltration, and parenchymal necrosis [292,293]. Capsaicin-sensitive C fibers release the proinflammatory neuropeptides substance P, CGRP, and neurokinin A294 [295]. These neuropeptides have been shown to promote inflammation and activate the transient receptor potential vanilloid 1 (TRPV1) receptor, which releases substance P and CGRP from afferent neurons and mediates inflammatory pain in many tissues [296].

In chronic pancreatitis, several neuropeptides and downstream receptor signaling are thought to contribute to pain. First, nerve growth factor is overexpressed in the pancreas and substance P and CGRP are overexpressed in the dorsal root ganglion in rodents [297] and humans [298], including enlarged pancreatic nerves in humans [299]. Second, because painful compared with painless human chronic pancreatitis was associated with a 3.5-fold increase in mast cells in pancreatic tissue [300], the same group proposed that mast cell degranulation products such as nerve growth factor may activate or sensitize nociceptive (sensory) neurons by activating proalgesic receptors and channels such as tyrosine kinase A (TrkA) and receptor potential family V receptor (TRPV1). As evidence supporting this possibility, antagonism of TRPV1, CGRP, and substance P receptors may suppress

pain in acute pancreatitis. Further, disruption of "neurogenic signaling," specifically substance P and neurokinin I receptor signaling, inhibits the inflammatory response and reduces the severity of experimental acute pancreatitis [301–303], similar to effects in other tissues [304]. Whether these interventions may have the same effect on inflammation and pain in human chronic pancreatitis is not known.

As a seemingly paradoxical observation, stimulation of other neural pathways may have an antiinflammatory effect in pancreatitis [305]. In an experimental model of acute pancreatitis, disruption of CCK-stimulated, efferent vagal cholinergic, nicotinic receptor signaling (by left unilateral cervical vagotomy or inhibition of nicotinic receptor signaling with mecamylamine) had a proinflammatory effect on disease and increased its overall severity. Conversely, agonism of this pathway with the selective α7 nicotinic receptor agonist GTS-21 had antiinflammatory effects on murine cerulein-induced pancreatitis and reduced its severity. The authors attributed these observations to efferent vagus neurotransmitter release of acetylcholine, interacting with nicotinic α7 acetylcholine receptors present on macrophages and neutrophils, resulting in the suppression of inflammatory mediators.

There is no clear explanation for the findings that capsaicin-sensitive vagal afferent pathways and specific vagal efferent pathways can have pro- and antiinflammatory effects. This question is fertile ground for future research. A study by Buscher and colleagues [306] provides evidence for pancreas-independent neural mechanisms of pain in chronic pancreatitis. According to their study, two mechanisms may contribute to painful chronic pancreatitis:

- persistent nociceptive input from ongoing pancreatic inflammation leads to central desensitization and visceral hyperalgesia
- continuing nociceptive input eventually alters central pain processing so that central pain perception becomes autonomous and independent of peripheral input.

These investigators used quantitative sensory testing to measure pain thresholds to pressure and electrical stimulation at various dermatomes in a small pilot study of 10 chronic pancreatitis patients on opioids. Thresholds were significantly lower in dermatomes associated with the pancreatic region, indicative of hyperalgesia of central origin. This type of pain may be less responsive to peripheral therapies aimed at the pancreas or peripheral nerve block but may be amenable to target disruption of central pain processing centers. This type of research is in its infancy. As one example, investigators are examining repetitive transcranial magnetic stimulation of the secondary somatosensory cortex [307] or secondary somatosensory area [308] to treat chronic visceral pain and transcranial direct current stimulation to treat chronic central pain [309].

Peripancreatic inflammation, involving the duodenum and retroperitoneum, may cause pain. Extension of active inflammation of the pancreatic tissue within the wall of the duodenum may result in extensive fibrosis and stenosis of the descending duodenum [310]. Peripancreatic inflammation may cause stenosis of the distal common bile duct, and this has been noted to be associated with severe abdominal pain. Pain may also result from continued inflammation of the head of the pancreas [310]. It is likely, therefore, that the pain in chronic pancreatitis is multifactorial. Depending on the etiological factors, structure, alteration, severity of the disease, and degree of pancreatic insufficiency, different factors may predominate in the genesis of pain. A study correlating pancreatic pathological condition and symptoms found that intermittent attacks of pain resulted from recurrent tissue necrosis, whereas chronic pain appeared to be secondary to segmental distention behind obstructed ducts [311].

Malabsorption

There is a 10-fold reserve for exocrine pancreatic enzyme secretion. Malabsorption occurs only after the capacity for enzyme secretion is reduced by more than 90% [269] (Fig. 69.2). In chronic pancreatitis secondary to alcoholism, it usually takes 10–20 years for severe pancreatic insufficiency to develop, but lipase secretion decreases more rapidly than secretion of proteolytic enzymes [270] (Fig. 69.3). Hence, steatorrhea is often an earlier and more severe problem than azotorrhea. The importance of colipase in fat malabsorption in adult patients is unknown, although colipase appears to be an important factor in children because steatorrhea and colipase correlate better than lipase and steatorrhoea [312].

Concurrent with the reduction of pancreatic enzyme secretion, there is also decreased bicarbonate secretion in patients with severe chronic pancreatitis. Not infrequently,

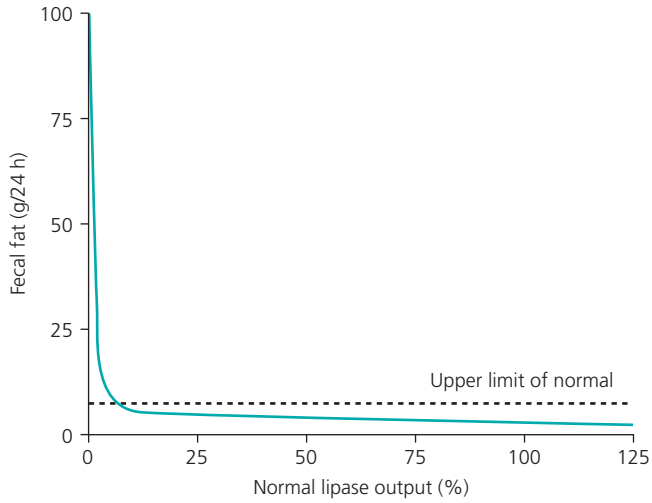

Figure 69.2 Relation between steatorrhea and lipase output. Steatorrhea does not occur until lipase output is reduced below 10% of normal. Adapted from DiMagno et al. [269].

the duodenal pH may fall to 4.0 or less [313,314] 90 minutes after eating. The abnormally low duodenal pH (less than 4.0) reduces lipid digestion by inactivating pancreatic enzymes and precipitating bile acids. These factors are important to consider in the treatment of pancreatic steatorrhea.

Diagnosis

Overview of diagnostic approaches

The diagnosis of chronic pancreatitis is usually suggested by historical information and then confirmed by radiography or laboratory tests. Over the years, an enormous number and variety of tests have been developed for the diagnosis of pancreatitis (Table 69.5). Many of these tests have not been adequately evaluated, and their true sensitivity and specificity are unknown. This section reviews many of the proposed tests for chronic pancreatitis; most are of limited clinical value. An understanding of the rationale underlying the test, however, often provides an insight into the physiological alterations that occur in chronic pancreatitis. The diagnosis of chronic pancreatitis can often be made on the basis of history and relatively simple radiographic tests. Only the rare patient requires extensive and complicated testing so the workup should be tailored to the individual patient.

Laboratory evaluation

Routine laboratory findings

Routine blood studies are not usually helpful in making the diagnosis of chronic pancreatitis.

Leukocytosis may be observed during acute exacerbations. The anemia frequently associated with malabsorption secondary to celiac disease is seldom present in patients with pancreatic malabsorption. Although patients with chronic pancreatitis commonly have an abnormal Schilling test result owing to the inability to digest R protein normally, megaloblastic anemia is rare [315]. Fat-soluble vitamin deficiency states (hypocalcemia, hypoprothrombinemia) are seldom observed in association with the steatorrhea of chronic pancreatitis, in contrast to their frequent occurrence in celiac sprue.

Cholestasis develops to varying degrees from compression of the common duct by a fibrotic process in the pancreas [316]. Alkaline phosphatase elevation in the absence of jaundice or other symptoms is the most common manifestation. Clinical jaundice results from more severe compression. Although liver disease is extremely common in alcoholics, this condition usually does not take the form of relatively pure cholestasis. The finding of cholestatic liver function in patients with pancreatitis requires extensive radiological testing, usually culminating in ERCP, to establish that the biliary obstruction results from chronic pancreatitis.

Specific tests for the diagnosis of chronic pancreatitis

The multiple tests available for the diagnosis of chronic pancreatitis can be separated into chemical measurements of pancreatic function and radiological procedures that provide information on pancreatic structure.

Several factors make it difficult to determine accurately the true sensitivity and specificity of these tests. First, biopsies of the pancreas are not usually obtained in patients with possible chronic pancreatitis, and most series report that patients have not been followed for a period sufficient to establish the

presence or absence of this condition with certainty. In most early or questionable cases, there is no histological gold standard that can be used to determine the accuracy of the more indirect chemical or radiological tests. Second, the sensitivity of the various diagnostic tests depends on the extent of the pancreatic damage. In long-standing disease with marked functional and anatomic alterations, virtually all proposed tests are positive. The sensitivity of the tests falls dramatically in early or mild chronic pancreatitis, however. The apparent sensitivity and specificity of the various tests also depend on the composition of subjects used to establish the normal range. For example, patients with a variety of disease states such as diabetes mellitus [317], celiac sprue [318], and cirrhosis [319] may have subnormal pancreatic secretion of enzymes. If such patients are used to establish the normal range, the lower limits of normal are reduced, and the sensitivity of the test for chronic pancreatitis drops accordingly. If the normal range is established with healthy controls, the specificity of a low secretion is reduced so although claims are made with regard to the sensitivity and specificity of tests for chronic pancreatitis, these claims have to be interpreted in light of the types of patients composing the pancreatitis groups as well as the subjects used to establish the normal range.

Serum pancreatic enzymes

In contrast to attacks of acute pancreatitis, in which the serum level of pancreatic enzymes is almost always elevated, serum enzyme levels may be elevated, normal, or low in chronic pancreatitis. In an acute exacerbation of the chronic process, the levels of these enzymes (amylase, lipase, trypsin) may be elevated; however, their serum concentrations seldom reach the levels observed in acute pancreatitis. A high serum concentration of pancreatic enzymes during a painful episode in a patient with advanced chronic pancreatitis should raise the possibility that some other abdominal process, such as gut perforation or infarction, is responsible for the pain.

Tests of pancreatic exocrine function

Tests of pancreatic exocrine function can be divided into those that directly assess pancreatic exocrine function (e.g., measurements of enzyme or bicarbonate secretion) and those that test some secondary effect of impaired enzyme secretion (e.g., malabsorption of a compound that requires pancreatic digestion for normal absorption).

Direct tests of pancreatic exocrine secretion

The basal secretory rate of the pancreas is highly variable so meaningful direct measurements of pancreatic secretion must be carried out in the stimulated state. Varying doses of secretin or CCK have been used for this purpose as well as a standard meal (the Lundh test). Early studies used simple drainage of the intestine at the ligament of Treitz to obtain pancreatic secretions. This technique does not recover all luminal fluid passing the collection site so studies have used a constant perfusion of a nonabsorbable marker, such as polyethylene glycol, into the duodenal bulb. Measurements of the concentration of this marker passing the distal collection site permit assessment of the rate at which fluid passes this site and make it possible to quantify the rate at which pancreatic secretory components pass this site [269].

A wide variety of pancreatic juice components, including the concentration or output of bicarbonate, amylase, lipase, and trypsin, have been assessed to find the most sensitive and specific indicator of chronic pancreatitis. In general, comparative studies suggest that all of them tend to be equally depressed in chronic pancreatitis and that there is no clear-cut advantage of one measurement over another. Few studies, however, measured pancreatic juice lipase output, which in two studies was less variable or was the earliest and most sensitive indicator of chronic pancreatitis, compared to lipase concentration, other enzyme concentrations/outputs, and bicarbonate concentration or output [320,321]. Critical to these studies was the use of continuous infusion rather than bolus administration of secretagogues. None of these measurements accurately differentiates chronic pancreatitis from carcinoma of the pancreas. Collection of pure pancreatic juice by way of cannulation of the ampulla of Vater during ERCP apparently adds little to the accuracy of the test [322].

Stimulation of pancreatic secretion has been produced over a wide range of doses and dosing schedules using secretin [323], CCK [324], cerulein [325], and bombesin [326] singly or in combination. Although it is difficult to compare the results of different studies, there appears to be no clear-cut advantage of one stimulatory technique over another. The relative value of direct stimulation of the pancreas with secretin-CCK vs indirect stimulation by a Lundh meal is also somewhat controversial, although most comparative studies suggest that direct stimulation is superior [327,328].

For many years, the finding of a subnormal pancreatic secretion of enzymes or bicarbonate in aspirated duodenal contents was considered the most sensitive test for chronic pancreatitis, and, if pancreatic carcinoma could be excluded, a low secretion was assumed to be diagnostic of chronic pancreatitis. Natural porcine secretin has been unavailable because its use for the treatment of autism has not been officially approved. Synthetic porcine secretin has been produced and compared favorably to natural porcine secretin in the diagnosis of chronic pancreatitis [329]. The sensitivity of the CCK or secretin pancreatic function tests was examined in 48 patients with suspected chronic pancreatitis [321]. All patients were evaluated with ultrasound, CT, and endoscopic retrograde pancreatography (ERP). All 10 patients with normal ERP results demonstrated normal function by direct hormonal stimulatory testing, and all 16 patients with advanced changes on ERP had grossly abnormal function testing. In 12 patients with mild to moderate changes on ERP, all demonstrated some abnormality of function, and of 10 patients with

minimal or equivocal changes on ERP, all had some degree of functional impairment. The CT and ultrasound were accurate in advanced chronic pancreatitis (94%–100%) but performed poorly in patients with less advanced changes on ERP (40%–50% accurate in patients with equivocal changes). This study is in agreement with other previous reports, which indicated that direct hormonal stimulation testing might be the most sensitive test (70%–95%) [330–334] for the diagnosis of chronic pancreatitis in all stages. As perhaps the strongest evidence, studies with definite histological evidence of chronic pancreatitis report a sensitivity of 67%–97% and specificity of 78%–100% [269,320,324,335–341]. However, it should be noted that patients with a variety of conditions, including diabetes mellitus [317], hepatic cirrhosis [319], Billroth II gastrectomy [342], and celiac sprue [318] may have diminished pancreatic secretory output with no clinical or radiological evidence of chronic pancreatitis. Another major consideration is that direct hormonal stimulation testing is only available at a few centers; therefore, the search continues for a convenient and readily available diagnostic test.

Indirect tests of pancreatic exocrine secretion

The complexity and patient discomfort involved in the direct measurement of pancreatic secretory capacity have led to a variety of simpler tests that indirectly assess the secretion of pancreatic enzymes. Most of these tests measure the absorption of some compound that first requires digestion by pancreatic enzymes. However, clinically detectable malabsorption of nutrients does not occur until pancreatic enzyme secretion has diminished to less than 10% of normal, so it is axiomatic that indirect tests of pancreatic function will not be able to detect early chronic pancreatitis and will therefore have very poor sensitivity.

The bentiromide test is used rarely and involves ingestion of *N*-benzoyl-L-tyrosyl-*p*-aminobenzoic acid (NBT-PABA), a tripeptide that is digested by chymotrypsin with the release of paraaminobenzoic acid (PABA) [343,344]. Free PABA is absorbed in the small bowel and excreted by the kidney; the quantity excreted in urine is used as a measure of pancreatic exocrine function. The sensitivity of the bentiromide test varies with the extent of damage to the exocrine pancreas, with sensitivity as high as 100% [345] reported with very severe disease and as low as 40%–50% with minor damage [346,347]. The specificity of this test is far from perfect. Reduced PABA excretion has been reported to occur commonly in diabetes mellitus [348], renal insufficiency [349], liver diseases [349], and malabsorption states other than pancreatic insufficiency, including celiac sprue [350], Crohn's disease [351], and postgastrectomy states [349]. The NBT-PABA test has low sensitivity so the major role of this test is not in diagnosis of chronic pancreatitis but rather in determining the extent of the pancreatic insufficiency that is present in patients with known chronic pancreatitis.

The demonstration that vitamin B-12 is malabsorbed in patients with pancreatic insufficiency, owing to their inability to degrade R protein [352], provided the rationale for a test for chronic pancreatitis. In this test, the subject ingests both [^{57}Co]cobalamin bound to intrinsic factor and [^{58}Co]cobalamin bound to R protein, plus excess intrinsic factor and a cobalamin analogue that saturates all empty R protein-binding sites [353]. Theoretically, the patient with pancreatic insufficiency should absorb the cobalamin bound to intrinsic factor much more efficiently than that bound to R protein. All other subjects should absorb both forms of cobalamin equally. Although the initial paper describing this technique reported excellent sensitivity and specificity for chronic pancreatitis, a subsequent study found very poor sensitivity [354].

Measurements of fecal chymotrypsin and elastase are rapid and simple but are inaccurate indicators of mild to moderate chronic pancreatitis. The diagnosis of pancreatic insufficiency by way of measurements of fecal chymotrypsin was first described 40 years ago [180] and a number of subsequent reports have evaluated the sensitivity and specificity of various modifications of the initial technique. The far more cumbersome measurement of total fecal chymotrypsin output in timed fecal collections appears to offer little advantage over the much simpler measurement of chymotrypsin concentration in a random fecal sample [180]. Reports of sensitivity of the test range from 45% [355] to 100% [356], depending on the extent of pancreatic damage in the study population. Specificity ranges from 49% [357] to 90% [358] with false-positive results reported for malabsorptive conditions such as celiac sprue, damage secondary to Crohn's disease, and postgastrectomy states [358,359].

Similar to fecal chymotrypsin, both the monoclonal and polyclonal enzyme-linked immunosorbent antibody fecal elastase-1 tests have unacceptably low sensitivity and specificity for diagnosing exocrine pancreatic insufficiency (see Chapter 139). For this reason, fecal chymotrypsin and elastase measurements are poor indicators of chronic pancreatitis in the clinic and in epidemiological studies [360]. Patients with appreciable chronic pancreatitis malabsorb fat when it is ingested in the form of triglyceride, and a number of indirect tests have been developed to assess such malabsorption. Most of these tests involve the administration of [^{14}C]olein. Hydrolysis of the triglyceride and absorption of [^{14}C]oleate lead to the production and pulmonary excretion of $^{14}CO_2$. Measurement of breath $^{14}CO_2$ excretion can be used as a simple measure of the normality of the hydrolysis of the labeled triglyceride [361]. Unfortunately, the test is negative in a high percentage of patients with early chronic pancreatitis, and false-positive results are observed in many malabsorption states other than chronic pancreatitis [362].

Imaging studies

The demonstration of diffuse, speckled calcification of the pancreas on a plain film of the abdomen is diagnostic of

chronic pancreatitis. Although the sensitivity of this finding is limited (perhaps 30%–40%), a plain film of the abdomen should be the first diagnostic test used when attempting to establish the diagnosis of chronic pancreatitis because a positive finding obviates the need for additional testing.

The development of ultrasound, CT, and ERCP has made it possible to assess, routinely, the gross structure of the pancreas. These tests all have excellent specificity and reasonably good sensitivity. Of major importance is the ability of these imaging procedures to differentiate between carcinoma of the pancreas and chronic pancreatitis. As a result, imaging techniques have largely supplanted tests of pancreatic function in the workup of the patient with possible chronic pancreatitis.

Ultrasound is the simplest and least expensive of the three imaging techniques. Findings on ultrasound that correlate with marked pancreatic changes on ERCP include dilation of the main pancreatic duct to more than 4 mm, large (more than 1 cm) cavities, and calcifications [363]. Findings associated with less severe changes on ERCP include dilation of the duct up to but not exceeding 4 mm, small cavities, reduction in echogenicity or echogenic foci in the parenchyma, and an irregular contour to the gland [363]. When a satisfactory ultrasound examination is obtained, the reported sensitivity of this test for chronic pancreatitis is of the order of 70%, and the specificity is high, roughly 90% [364–367]. The finding of chronic pancreatitis on ultrasound usually requires no additional confirmatory testing.

CT is 10%–20% more sensitive than ultrasound for the diagnosis of chronic pancreatitis [366–368]; these two techniques have roughly comparable specificities. CT is more expensive than ultrasonography and involves exposure to ionizing radiation. Therefore, in the workup for chronic pancreatitis, CT should usually be limited to patients who have negative or unsatisfactory ultrasound examinations. The most common diagnostic findings of chronic pancreatitis on CT include duct dilation, calcifications, and cystic lesions [369–371] (Fig. 69.4). Less common diagnostic findings include enlargement or atrophy of the pancreas and heterogeneous density of the parenchyma. This imaging technique is particularly helpful in the differentiation of chronic pancreatitis from carcinoma of the pancreas. The dilated duct system resulting from carcinoma tends to be smooth or beaded, in contrast to the irregular, calcified ducts that are typical of chronic pancreatitis. The sensitivity of CT for the diagnosis of chronic pancreatitis is in the neighborhood of 80%, whereas the specificity is roughly 90% [366,372,373]. ERCP is commonly considered to be the most sensitive and specific test available for the diagnosis of chronic pancreatitis even though there are few comparisons between ERCP and histopathology [337–339], in contrast to the numerous studies that provide diagnostic accuracy of direct pancreatic function tests by using gold standard histopathology (see Table 139.3 in Chapter 139) [269,320,324,335–341]. Furthermore, ERCP has become the gold standard against which all other tests are evaluated. In the absence of histological confirmation of disease in most patients, it is difficult to speak with complete certainty about the diagnostic accuracy of ERCP (because ERCP is the gold standard). Most studies indicate that the sensitivity and specificity of ERCP are 70%–90% and 80%–100%, respectively [321,373–376].

Figure 69.4 Chronic pancreatitis. Computed tomography scan shows pancreatic atrophy along with multiple intraductal calculi and dilation of the pancreatic duct (arrow).

The most commonly used classification of ERCP changes in chronic pancreatitis was developed at an international symposium. The Cambridge classification of chronic pancreatitis is based on abnormalities seen in the main pancreatic duct and in the side branches [377,378] (Table 69.6). In minimal pancreatitis, the changes are limited to the branches and fine ducts (less than three), which show dilation and irregularity (Fig. 69.5). There is considerable observer variation in the detection of these minor changes, and differentiation of normal from abnormal is not always clear. Minor ductal dilation and intraductal calculi mimicking the changes seen in chronic pancreatitis are observed with aging (age > 60 years) [379], as found in postmortem pancreatograms [380–383], and following acute pancreatitis [376,384]. Indeed, ductal changes occur and commonly persist in 9%–33% of patients after acute pancreatitis [376,384] but likely represent scars rather than a specific sign of chronic pancreatitis as they rarely lead to reduced pancreatic function or definite or prob-

Table 69.6 Cambridge classification of chronic pancreatitis by endoscopic retrograde pancreatography

Grade	Main pancreatic duct	Side branches
Normal	Normal	Normal
Suggestive	Normal	< 3 abnormal
Mild	Normal	≥ 3 abnormal
Moderate	Abnormal	> 3 abnormal
Severe	Abnormal plus at least one of the following: – Large cavity – Duct obstruction – Dilation or irregularity – Intraductal filling defects

Figure 69.5 Endoscopic retrograde cholangiopancreatography study shows minimal changes consistent with chronic pancreatitis. The main duct is slightly irregular, and the branches are slightly dilated. These findings are not diagnostic.

able evidence of chronic pancreatitis at follow-up [376,384]. Further, 50% of patients with mild ERCP changes may not have histological evidence of chronic pancreatitis [381,385]. Moderate pancreatitis is characterized by abnormalities in at least three or more side branches and the additional finding of dilation, tortuosity, and stenosis of the main pancreatic duct (Fig. 69.6). Advanced pancreatitis has the additional findings of cyst formation, duct obstruction, severe ductal dilation, or irregularity (Fig. 69.7). Pancreatic carcinoma usually can be distinguished from chronic pancreatitis in that there is a single strictured region in malignant obstruction, in contrast to the multiple stenoses, irregular branching ducts, and intraductular calculi observed in chronic pancreatitis.

In general, there is a good correlation between the changes observed on ERCP and measurements of pancreatic secretory

Figure 69.6 Endoscopic retrograde cholangiopancreatography study shows changes of moderate pancreatitis. The main duct is irregular and dilated, and there is a pseudocyst in the tail of the pancreas.

capacity. An occasional patient, however, may have markedly diminished secretory function with seemingly minor changes on ERCP. Patients with minor abnormalities on ERCP often have normal secretory function. For further discussion please see Chapter 139.

It should be noted that pancreatitis occurs in about 5% of patients undergoing ERCP [386]. This risk for pancreatitis increases significantly in female patients with normal serum

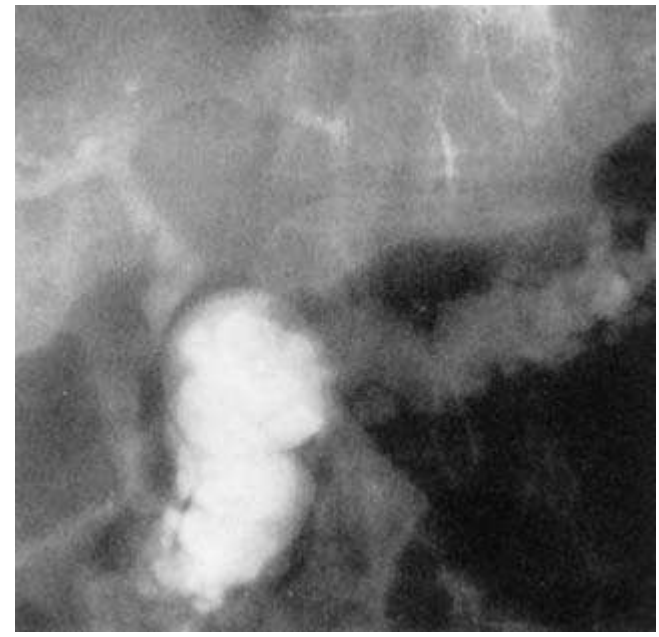

Figure 69.7 Endoscopic retrograde cholangiopancreatography study shows changes of advanced chronic pancreatitis. There are massive cystic dilations of the main duct and its branches.

bilirubin, patients suspected of sphincter of Oddi dysfunction, and those with a previous history of post-ERCP pancreatitis [386]. In fact, patients with the least probability of harboring truly obstructive pathology are at the highest risk for pancreatitis after ERCP, even if the procedure is for diagnosis alone. ERCP is an expensive procedure and has a low but not insignificant rate of associated complications, so this test ordinarily should be reserved for the rare patient with chronic pancreatitis in whom the diagnosis cannot be clearly established using other imaging techniques.

Although chronic pancreatitis and carcinoma of the pancreas usually can be reliably distinguished based on imaging studies, in an occasional patient, this differentiation may be difficult [387]. Attempts to use serum or pancreatic juice tumor markers, such as CA 19-9, to differentiate benign from malignant pancreatic processes have not been impressive [387], and it is usually necessary to make a tissue diagnosis. Although laparotomy with open biopsy was required in the past, percutaneous fine-needle aspiration biopsy makes it possible to obtain a histological diagnosis in a very high percentage of patients with pancreatic carcinoma. Under CT or ultrasonographic guidance, a small-gauge needle is inserted into the pancreatic mass, and aspirated material is examined for the presence of malignant cells. The reported specificity of this test approaches 100%, and the sensitivity is 80%–90% [388].

In recent years, advances in magnetic resonance (MR) imaging have led to the development of MR cholangiopancreatography (MRCP) for the evaluation of the biliary and pancreatic ducts (Fig. 69.8). Similar to ERCP, MRCP allows direct visualization of the pancreatic duct but without radiation exposure or the use of oral or intravenous contrast. Hence, it can be used in patients who are pregnant or have contrast allergies. In severe chronic pancreatitis with marked changes of the main pancreatic duct, agreement between MRCP and ERCP is excellent [389–392]. However, MRCP is relatively insensitive in mild chronic pancreatitis, in which changes are limited to the secondary ducts. Emerging modifications and application of MRCP technology, including secretin-enhanced MRCP and "diffusion-weighted" MR imaging, are under investigation and are reviewed in Chapter 132.

Endoscopic ultrasonography (EUS) is a major advance in imaging the pancreas because it may provide more detailed structural information of the pancreas than routine ultrasonography and CT scanning [393]. EUS features of chronic pancreatitis may be used to establish the diagnosis and evaluate the severity of the disease [394]. These include ductal changes and parenchymal changes, such as echo texture of the gland, calcifications, lobulations, and bands of fibrosis (Figs 69.9 and 69.10; see Table 69.7). For EUS to be considered an accurate test for chronic pancreatitis, there must be good interobserver agreement. To address this issue, EUS was performed on 33 patients with suspected chronic pancreatitis based on typical symptoms as well as on 12 control patients [395]. There was moderately good overall agreement for the final diagnosis of chronic pancreatitis ($\kappa = 0.45$). Agreement was good for individual features of duct dilation ($\kappa = 0.6$) and lobularity ($\kappa = 0.51$) but poor for the other seven features ($\kappa < 0.4$). The presence of stones was considered the most predictive feature of chronic pancreatitis, followed by visible side branches, cysts, lobularity, irregular main pancreatic duct, hyperechoic foci, hyperechoic strands, main pancreatic duct dilation, and main duct hyperechoic margins. Hence, EUS

appears to be a reliable method for the diagnosis of chronic pancreatitis, with good interobserver agreement among experienced endosonographers. A prospective evaluation of EUS compared with ERP and the secretin stimulation test in the diagnosis of chronic pancreatitis was conducted by Catalano and colleagues [394]. Eighty consecutive patients with recurrent pancreatitis participated in the study. EUS criteria for chronic pancreatitis included mild (one to two features), moderate (three to five features), and severe (more than five features; see Table 69.7). Abnormal EUS, ERP, and secretin test were observed in 63, 36, and 25 patients, respectively. The secretin test had 100% agreement with normal and severe chronic pancreatitis by EUS criteria, but agreement was poor for mild (13%) and moderate (50%) disease. On the other hand, the agreement between ERCP-specific and EUS-specific criteria was excellent for normal (100%), moderate (92%), and severe (100%) chronic pancreatitis and poor for mild (17%) disease. The main source of disagreement in this and other studies involves patients with abnormal results of EUS and normal ERCP or pancreatic function tests. Therefore, it appears that with the exception of mild changes noted on EUS, there is excellent agreement between EUS and ERCP in the diagnosis of chronic pancreatitis. Similar findings were reported in another prospective study to determine the ability of EUS to diagnose, exclude, or establish the severity of chronic pancreatitis found by ERP [396]. In general, histology is the most obvious candidate for a diagnostic gold standard, but few studies have compared EUS with pancreatic histology. In a preliminary study comparing EUS with the histological features of chronic pancreatitis in 34 patients who underwent EUS and later pancreatic surgery (21 with chronic pancreatitis and 13 with pancreatic carcinoma), the sensitivity of EUS for diagnosis of chronic pancreatitis was 78%, specificity was 73%, and the threshold for diagnosis was four or more echo features [397]. However, these findings are only applicable to mostly severe pancreatitis. The specificity of EUS changes in mild or early chronic pancreatitis is unknown but probably very low. Reliance on a few EUS criteria, such as inhomogeneity, hyperechoic strands, and lobularity, probably would give rise to many false diagnoses of chronic pancreatitis. Long-term follow-up of patients with mild EUS changes is needed to determine the usefulness of EUS in diagnosing mild chronic pancreatitis. In a recent study, 130 patients with a history of chronic use of alcohol and recurrent abdominal pain underwent ERCP and EUS [398]. All patients with chronic pancreatitis confirmed by ERCP (70.8%) had ductal or parenchymal changes detected with EUS. Among 38 patients (29.2%) with normal ERCP, 32 (84.2%) presented with morphological features consistent with chronic pancreatitis by EUS. During follow-up (median, 18 months), chronic pancreatitis was confirmed by repeat ERCP in 22 of these 32 patients (68.8%). Hence, it appears that EUS is more sensitive than ERCP in the detection of early chronic pancreatitis in patients with abdominal pain and a history of chronic and continued ingestion of alcohol. More long-term follow-up studies are needed to determine the usefulness of EUS in diagnosing mild nonalcoholic chronic pancreatitis.

Rational use of tests in the diagnosis of chronic pancreatitis

The evaluation should begin with a plain film of the abdomen. The finding of pancreatic calcification is virtually diagnostic of chronic pancreatitis, and no further testing is required. If calcifications are not present, the next test should be ultrasound. Once again, if this test demonstrates findings

indicative of chronic pancreatitis, further procedures are not necessary. If the ultrasound examination is nondiagnostic, CT is indicated only if there is a high degree of clinical suspicion of chronic pancreatitis. Only a small percentage of patients with chronic pancreatitis have negative ultrasound and CT findings. Thus, ERCP should be reserved for those patients in whom the diagnosis of chronic pancreatitis is thought to be likely on clinical grounds or for patients in whom ultrasound, CT, and fine-needle biopsy have not been able to differentiate between carcinoma of the pancreas and chronic pancreatitis. If ultrasound, CT scan, and ERCP are normal, a secretin test may disclose evidence of mild chronic pancreatitis. Unfortunately, the secretin test is not widely available. Studies suggest that EUS may be useful to establish the diagnosis and evaluate the severity of the disease. Additional studies are needed to define the sensitivity of EUS for the diagnosis of early disease. MRCP may be used as a backup alternative if ERCP fails and EUS is unavailable or technically not feasible, such as in patients with a Roux-en-Y gastrojejunostomy.

Complications

Pseudocyst

A pseudocyst is a collection of pancreatic juice, outside the normal boundaries of the ductal system, which is enclosed by a fibrous tissue membrane. It is the most common complication of chronic pancreatitis, occurring in up to 25% of cases in some series [399]. Most chronic pseudocysts occur in patients with chronic alcoholic pancreatitis [400], and they are found more commonly in the body of the pancreas than in the head or tail [400].

Little is known about the mechanism responsible for the initial formation of pancreatic pseudocysts. They probably result from rupture of a pancreatic duct, activation of interstitial pancreatic juices, necrosis of the surrounding parenchyma, escape of the pancreatic juice into the lesser sac, and reaction of local mesothelial cells to wall off the collection with a fibrous membrane. Once initiated, expansion of the embryonic pseudocyst continues until the surrounding tissue pressure equals pancreatic secretory pressure, which is usually elevated in chronic obstructive pancreatitis. Although not conclusively demonstrated, some evidence exists to suggest that pancreatic juice contained within a pseudocyst can exchange with plasma. If so, this may represent a mechanism responsible for resorption of immature pseudocysts and spontaneous resolution of chronic pseudocysts.

Pain is the major symptom of pancreatic pseudocysts. A pseudocyst should be suspected in a patient with stable chronic pancreatitis who experiences worsening of abdominal pain. Abdominal ultrasonography is most frequently used in the diagnosis and management of pseudocysts. It is best used as a serial monitor of pseudocyst size in those patients in whom definitive drainage is delayed. CT has emerged as the single most accurate method of diagnosing pancreatic pseudocysts [401]. In addition to its high accuracy rate, it is capable of providing structural details, such as the size of the common duct or pancreatic duct. This has important bearing on the choice of an operative approach. In the presence of dilation of either or both the common bile duct and pancreatic duct, drainage of the pseudocyst alone is rarely sufficient [402]. Although some surgeons have advocated ERCP for all patients with pseudocysts [403,404], others have not found routine preoperative pancreatography desirable for fear of secondary infection, which may occur in up to 25% of cases [404]. It is generally agreed, however, that patients with suspected concomitant common duct obstruction should undergo ERCP before surgical drainage.

In contrast to acute pseudocysts, chronic pseudocysts, especially those larger than 6 cm, almost never resolve spontaneously [405,406]. On the other hand, they also do not carry the same risk for serious complications as acute pseudocysts. In a study involving 75 patients with chronic pancreatitis and pseudocyst, about half of the patients could be managed conservatively [407]. Only one pseudocyst-related complication occurred in this group, and there was no mortality. According to this study, indications for operative management include persistent abdominal pain, enlargement, or complications of pseudocyst.

Effective treatment of a pseudocyst includes excision and internal or external drainage. Surgical excision provides definitive treatment and is feasible when the cyst is localized to the tail of the pancreas. In most cases, however, internal drainage is the treatment of choice. Pseudocysts that are more than 6 weeks old usually have a mature cyst wall that permits internal drainage, where the cyst is anastomosed to the stomach (cystogastrostomy), duodenum (cystoduodenostomy), or jejunum (cystojejunostomy). The fluid in the pseudocyst drains into the gastrointestinal tract, and the cyst cavity collapses and becomes obliterated, usually within 1 week. There also have been reports of endoscopic drainage for the treatment of pseudocysts in chronic pancreatitis [408,409]. A pseudocyst that indents the stomach or duodenum can be punctured transendoscopically using electrocautery or lasers to create a fistulous tract between the pseudocyst and the stomach or duodenum. Long-term, endoscopic studies report 62%–84% success rates [410–413] compared to surgical success rates of 90%–93% [411,414,415]. In a medium-term follow-up study, Cremer and colleagues [408] reported a success rate of 96% for endoscopic cystoduodenostomy and 100% for endoscopic cystogastrostomy in 33 patients with chronic pancreatitis. No significant complications were observed after successful endoscopic cystoduodenostomy, and the two complications of endoscopic cystogastrostomy were gastric hemorrhage and iatrogenic pseudocyst infection. To decrease the risks for bleeding and

perforation, the use of endosonography-guided drainage of a pancreatic pseudocyst has been reported [416]. Potentially, the precise ultrasonographic definition of the cyst and local anatomy at the time of endoscopic drainage may improve the safety of endoscopic drainage, but the results are too preliminary for adequate evaluation.

External drainage usually is used for patients with infected pseudocysts and for those in whom the wall of the pseudocyst is not mature enough to hold sutures. Drainage is achieved by surgical placement of a large catheter in the pseudocyst, and the fluid drains externally through the abdominal wall. This form of treatment usually is safe but is associated with a higher recurrence rate than internal drainage [417].

CT-guided, percutaneous, transabdominal catheter drainage of chronic pseudocysts has gained popularity and is considered by some a preferred alternative to surgical treatment in the management of pancreatic pseudocysts. Van Sonnenberg and colleagues [418] reported a 90% success rate in the percutaneous drainage of 101 pancreatic pseudocysts. The mean duration of drainage was 20 days. There was no mortality, and the only major complication was superinfection in four cases. Adams and Anderson [419], in a retrospective study, also found that percutaneous catheter drainage was as effective as internal drainage in the management of pseudocysts, although drain tract infection was as high as 48%. In a long-term retrospective study of 42 patients undergoing percutaneous catheter drainage, however, Criado and associates [420] reported that in nine patients, the pseudocysts failed to resolve, and seven recurred after initial resolution. Hence, the effectiveness of percutaneous drainage in the management of pseudocysts remains to be established.

Somatostatin is a potent inhibitor of pancreatic secretion and therefore may be useful in the treatment of pancreatic pseudocyst. Gullo and Barbara [421] reported that 2-week treatment with octreotide, a long-acting somatostatin analogue, resulted in a 42% reduction in size of the pseudocysts in four of seven patients. In addition, octreotide also appears to be effective in decreasing persistent catheter drainage from chronic pseudocyst [422,423]. Therefore, patients with pancreatic pseudocyst resistant to drainage should be offered a course of octreotide before surgery is contemplated.

Pancreatic ascites

The incidence of pancreatic ascites in chronic pancreatitis is usually considered to be less than 1%. It occurs as a consequence of persistent leakage of pancreatic juice from a pseudocyst or the pancreatic duct. Fifteen percent of patients with a pseudocyst may have pancreatic ascites [424]. On the other hand, 60% of patients with pancreatic ascites have pseudocysts [425,426]. Pancreatic ascites occurs typically in alcoholic patients with cirrhosis, who may complain of mild to moderate abdominal pain because of distention. The diagnosis is often erroneously attributed to decompensated cirrhosis; however, paracentesis reveals elevation of pancreatic enzyme levels and a high total protein or albumin level. These findings are diagnostic.

Most patients need surgery. A period of 2–3 weeks of observation and medical treatment is warranted. During this period, the patients are given nothing orally and are placed on parenteral nutrition to improve their nutritional status. Suppression of pancreatic secretion by agents such as octreotide may be tried (100–250 μg subcutaneously every 4 hours). With this regimen, the ascites may resolve spontaneously in up to one-third of patients, and surgery can be avoided. For patients who require an operation, ERCP should be performed to identify the precise site of the leak.

Pancreatic fistula

External pancreatic fistula as a complication of chronic pancreatitis is rare. It occurs most commonly after operative or percutaneous drainage of a pseudocyst. It also may follow pancreatic biopsy or arise from a leaky pancreatic anastomosis. Clinically, pancreatic fistula should be suspected when clear fluid drains from a cutaneous orifice, and the diagnosis is confirmed when the amylase content of the fluid is found to be elevated. Treatment is conservative and consists of fluid and electrolyte replacement, nutritional support, and eradication of infection if present. Somatostatin, which suppresses pancreatic secretion and decreases the volume of fistula drainage, may be used. During the course of therapy, a fistulogram should be obtained when the tract is well formed. If there is ductal obstruction between the site of the leak and the duodenum, surgical repair may be necessary. Most of the fistulae, however, close spontaneously.

Splenic vein thrombosis

Splenic vein thrombosis with extrahepatic (sinistral) portal hypertension is a well-known complication of chronic pancreatitis [427,428]. The splenic vein courses along the posterior surface of the pancreas so thrombosis may occur as a result of peripancreatic inflammation associated with acute attacks or with pseudocyst formation and extension. Rosch and Herfort [429] found occlusion of the splenic vein in about 4% of cases of chronic pancreatitis studied with splenoportography. Almost all patients had some impingement on the splenic vein. Varices involving the esophagus, stomach, duodenum, and colon have been described with resultant hemorrhage. A more recent study [428] involving 484 consecutive patients with chronic pancreatitis reported that splenic vein thrombosis occurred in 7% (34 patients), of whom 35% (12 patients) had gastroesophageal varices. Overall, 18% of them bled either before first surgery or on follow-up. The 22 patients who underwent splenectomy never bled after surgery. These findings support the recommendation that patients who have symptomatic sinistral portal hypertension who are undergoing surgery should have concomitant splenectomy. Splenectomy also should

be strongly considered in patients undergoing surgery for chronic pancreatitis who have varices secondary to splenic vein thrombosis regardless of the presence or absence of a previous history of variceal bleeding.

Treatment

Treatment of chronic pancreatitis is aimed mainly at the control of pain and the correction of malabsorption with adequate pancreatic enzyme replacement. Clinical diabetes occurs relatively late in the disease, and insulin is usually needed for its management.

Control of pain

The management of pain in chronic pancreatitis can be a challenging problem. It is the symptom that most commonly prompts the patient to seek medical attention and is the one that is most difficult to manage. Pain patterns are highly variable, and this may reflect different causative mechanisms. The problem is further exacerbated by a lack of good controlled trials. As highlighted in an American Gastroenterological Association technical review on treatment of pain in chronic pancreatitis [430,431], "a reliable database for making sound judgements and recommendations is lacking in most areas."

Avoidance of alcohol

A long-held clinical aphorism is that avoiding alcohol ingestion decreases the frequency and severity of abdominal pain in chronic alcoholic pancreatitis. Trapnell [385] reported that 75% of his patients with chronic alcoholic pancreatitis experienced pain relief when they stopped drinking. This observation may be explained by the stimulatory effect of alcohol on pancreatic secretion [432]. The relationship between alcohol and pain in chronic pancreatitis, however, is controversial. Bornman and colleagues [432] noted that half of their patients with painful pancreatitis and half of their patients with painless pancreatitis continued to drink. Similar observations were made by Marks and associates [433]. These findings call into question whether continued alcohol ingestion is related to pain. It is conceivable that pancreatic pain is related to exocrine pancreatic secretion. In patients who maintain significant exocrine secretory function, pain may be provoked by alcohol, which acts as a secretagogue. In patients whose exocrine secretion is drastically reduced, alcohol no longer plays a role in the mechanism of pain. Further studies are needed to clarify the role of alcohol in pain production.

Analgesics

Analgesics remain the main method for pain control in chronic pancreatitis. Initially, nonnarcotic analgesics, such as salicylates or acetaminophen, should be used. Preferably, these analgesics should be given before meals to prevent postprandial exacerbation of pain. Drug doses should be individualized, and the lowest effective dose should be used. As the severity of pain increases, the dose strength or frequency of these simpler analgesics should be increased before switching to narcotics. In severe cases, however, opiate analgesics are required, and they should not be withheld for fear of narcotic addiction.

Celiac plexus block

Percutaneous, radiologically or ultrasonographically guided, celiac ganglion alcohol injection has been used for control of pancreatic pain. This technique has been helpful in patients who have severe pancreatic pain secondary to pancreatic cancer [434]. In small, uncontrolled series of patients with chronic pancreatitis and debilitating pain this procedure has produced mixed results. The occasional benefits almost never last for more than a few months [435], and repeated treatment may not be as effective. The risk for procedure-induced transient hypotension, nerve root pain, and focal neuropathic damage, combined with the need for repeated blocking, even if successful, make this an unattractive technique for most patients [435]. An open trial of celiac plexus block using botulinum toxin A instead of alcohol was unsuccessful [436].

The advances in EUS have allowed the performance of celiac plexus block under the guidance of EUS. This has become a relatively simple and short outpatient procedure. Because of the anterior transgastric approach taken during the procedure, it has mostly eliminated the risk for nerve or spinal cord injury. A prospective study with EUS-guided celiac plexus block was performed in 90 patients with painful chronic pancreatitis [437]. A significant improvement in pain score occurred in 55% of patients. Unfortunately, the benefit persisted beyond 24 weeks in only 10%. Hence, although EUS-guided celiac plexus block is safe and well tolerated, it is not very effective for treating pain in chronic pancreatitis because it offers only temporary relief.

Enzyme therapy

Much interest has been generated by a series of observations suggesting that the intraluminal action of pancreatic proteases plays an important role in regulating pancreatic enzyme secretion. The underlying concept of feedback regulation of the pancreas is based primarily on studies in rats that showed that diversion of pancreatic juice from the duodenum stimulates CCK release and pancreatic enzyme secretion [438,439]. On the other hand, intraduodenal administration of trypsin or chymotrypsin inhibits the release of CCK and pancreatic enzyme secretion. The increased plasma CCK levels and pancreatic secretion after diversion of pancreatic juice appears to be mediated by a trypsin-sensitive substance secreted by the proximal small intestine that has been designated CCK-releasing factor [440]. When trypsin is present, this peptide is

cleaved and inactivated. The CCK-releasing factor may act as a mediator of pancreatic enzyme secretion in response to dietary protein intake in rats. Dietary protein in the intestine competes for the trypsin that would otherwise inactivate CCK-releasing factor [441]. The resulting increase of CCK-releasing factor in the intestinal lumen enhances CCK release, stimulating pancreatic enzyme secretion. A number of CCK-releasing peptides have been identified. These include a peptide extracted from porcine intestinal extracts with a structure identical to the diazepam-binding protein [442] and a luminal CCK-releasing peptide isolated from the duodenal secretion of rats [443]. The physiological significance of these releasing peptides is yet to be defined.

The protease-sensitive feedback mechanism was first reported to occur in humans in 1977 [444]. Subsequently, several groups of investigators confirmed that intestinal administration of trypsin or chymotrypsin inhibits pancreatic enzyme secretion [444–448]. Thus, it is conceivable that in patients with chronic pancreatitis, decreased enzyme secretion may result in the hyperstimulation of the pancreas by elevated plasma CCK levels, with resultant pain. Some [449–451], but not all [452,453], studies reported elevated plasma CCK levels in patients with chronic pancreatitis. It has been proposed that effective enzyme replacement therapy should reduce pancreatic stimulation, decrease intraductal pressure, and diminish pain. This hypothesis was tested in several clinical studies. In a double-blind, crossover study, Isaksson and Ihse [454] reported pain relief in 15 of 19 patients with chronic pancreatitis. There was a 30% reduction in pain intensity and a significant decrease in the frequency of pain attacks in patients on active enzymes. Slaff and colleagues [445] studied 20 patients with painful chronic pancreatitis in a double-blind, crossover study. Pain reduction was observed in 9 patients with mild to moderate pancreatic insufficiency, whereas only 2 of 11 with severe insufficiency responded to the treatment with enzyme replacement. Most of the good responders were women with idiopathic chronic pancreatitis, whereas most of the poor responders were men with alcohol-induced chronic pancreatitis. Favorable response was also reported by Ramo and associates [455], who showed significant pain relief after self-administration (ad libitum) of an enzyme preparation, compared with administration of the regular dose in 10 patients with painful chronic pancreatitis. These three double-blind studies [445,454,455] demonstrated good results for enzyme treatment in 73% (36 of 49) of the patients evaluated. A double-blind, 4-week crossover study from Denmark, however, showed that oral administration of two capsules of Pancrease with each meal did not significantly control pain compared with placebo [456]. Another multicenter 2-week controlled study in more than 40 patients using an enteric-coated supplement also showed no benefit [457]. Feedback inhibition of pancreatic enzyme secretion depends on delivery of high concentrations of protease to the duodenal lumen. Enteric-coated preparations preferentially release most of their enzymes distal to the duodenum and may therefore be less effective at suppressing CCK levels and producing pain relief [458]. Finally, a 4-month double-blind, crossover study used an enteric-coated preparation with microspheres that release their contents at a lower pH (pH > 5.0) than most commonly used microspheres (pH > 6.0). Despite a high delivery rate of trypsin into the duodenum, this study showed no benefit in pain scores in patients receiving pancreatic enzymes compared with placebo [459]. However, this study contained a small number of women and evaluated patients with recurrent rather than chronic pain. Long-term trials comparing nonenteric and enteric-coated preparations in patients stratified according to etiology, severity, and pattern of disease should help to clarify these issues. Until then, it seems reasonable to initiate a trial of high-dose, nonenteric-coated oral pancreatic enzymes taken with meals for several weeks in any patient with painful chronic pancreatitis. The best results may be seen in pancreatitis of nonalcoholic etiology, with symptoms of constant, rather than recurrent, pain and only mild to moderate pancreatic insufficiency [460].

Treatment with octreotide

Somatostatin is a naturally occurring hormone that has been shown to inhibit pancreatic secretion [461]. Theoretically, it may also have cytoprotective action and beneficial effects on the reticuloendothelial system in the setting of pancreatic inflammation [462–464]. In addition, clinical studies have shown that somatostatin has antinociceptive activity in human [465,466] and animal [467,468] models of pain, suggesting that this peptide may be helpful for pain control in chronic pancreatitis. Somatostatin also appears to gain its beneficial effects in inflammatory conditions through its inhibition of cytokine release. In a recent study, somatostatin was shown to reduce markedly the secretion of interleukin-8 and interleukin-1 from intestinal epithelial cells [469]. In another study, somatostatin significantly inhibited interleukin-8 and interferon-γ production from activated peritoneal macrophages [470].

Octreotide is a synthetic, long-acting analogue of somatostatin that has been shown to inhibit CCK release and both basally and neurally stimulated pancreatic secretion [471–473]. Octreotide's long duration of action allows subcutaneous dosing and makes it a more practical alternative for the treatment of chronic pancreatitis than the short-acting native somatostatin. The drug is well tolerated, although long-term therapy predisposes to cholesterol gallstones. Unfortunately, controlled trials using octreotide for the pain of chronic pancreatitis are limited. Short 3-day studies, using 100 μg and 150 μg three times a day, showed no benefit [474]. A multicenter randomized 4-week study of 91 patients with advanced chronic pancreatitis and severe pain was performed [475]. Octreotide, at doses ranging from 40 μg to 200 μg three times daily, was compared with placebo. Although results in this

pilot study did not reach statistical significance, 200 μg three times a day of octreotide produced the greatest pain relief (65% vs 35% of patients with placebo), especially in patients with constant as opposed to intermittent pain. Additional studies are needed to clarify the role of octreotide in the management of chronic pancreatitis pain.

A long-acting formulation of octreotide acetate (Sandostatin LAR Depot) was developed for patients requiring long-term octreotide therapy. It consists of octreotide acetate microencapsulated by a biodegradable polymer. Drug release occurs slowly because cleavage of the polymer takes place primarily through tissue fluid hydrolysis. After single intramuscular injection, the serum octreotide reaches plateau concentrations at about day 14 and remains relatively constant during the following 3–4 weeks. This long-acting form of octreotide may provide significant benefit over octreotide because it requires only monthly injection. This should be prospectively evaluated with a double-blind, randomized, multicenter study.

Endoscopic therapy

Endoscopic therapy has been used for control of pain in chronic pancreatitis, with the aim of alleviating obstruction of flow caused by ductal strictures, stones, or papillary stenosis. Ductal strictures are sometimes treated by balloons or dilating catheters, but in most cases, dilation is followed by stent placement across the stricture. Technical success in reported studies ranges from 82% to 100% [476–482] and pain improvement occurs in 55%–100% of patients during a follow-up of 8–39 months. True success rates are difficult to decipher, however, because stent placement frequently was performed with other procedures. Ponchon and colleagues [482] used a standardized protocol to evaluate endoscopic stenting for pain relief in a highly selected subgroup of patients with chronic pancreatitis. Patients with multiple strictures, pancreatic calculi, pancreatic divisum, common duct narrowing, any duodenal impingement, or a pseudocyst larger than 1 cm were excluded. They successfully placed 10-French, multi-side-hole stents after biliary and pancreatic sphincterotomy and balloon dilation of strictures in 28% of 33 patients (85%) with a distal pancreatic duct stricture and upstream dilation. The stents were exchanged at 2-month intervals, for a total stenting duration of 6 months. The report was based on 23 patients observed for at least 1 year after removal of the stent. During the stenting period, 21 patients (91%) had resolution or reduction in pain, and 17 discontinued analgesic medications. Twelve patients (52%) had a persistent beneficial outcome for at least 1 year after stent removal. Disappearance of the stenosis on pancreatography, at stent removal, and 1 year later and reduction in the diameter of the pancreatic duct were significantly associated with relief of pain. Caution, however, should be urged to avoid extrapolating these observations to widespread use of endoscopic therapy, which may expose patients to greater risks than proven benefit. According to guidelines published by the American Society of Gastrointestinal Endoscopy [483], the diameter of the pancreatic duct or resolution of pancreatic duct strictures in response to endoscopic therapy does not correlate with resolution of pain [483]. Furthermore, what data are available is difficult to interpret because "Confounding the literature on pancreatic duct stent therapy are other therapies performed at the same time of stent placement and the tendency of the chronic pancreatitis pain to wax and wane and decrease with time as deterioration of the pancreas function occurs" [483].

Based on reports in the literature, the incidence of occlusion of pancreatic stents appears to be similar to that for biliary stents [484]. Sherman and Lehman [485] reported that 50% of pancreatic stents (5–7 French) were occluded within 8 weeks of placement. Another complication is stent migration, which may be upstream (into the duct) or downstream (into the duodenum). Migration in either direction may be heralded by return of pain or pancreatitis. Johanson and associates [486] reported inward migration in 5.2% of patients and duodenal migration in 7.5%. Modifications in the design of pancreatic stents may reduce the frequency of such occurrences [487]. Long-term studies of stent placement also indicated that morphological changes occurred in most patients. These were usually mild and were reversible in most patients [488,489].

There are two prospective, randomized trials comparing endotherapy and surgery for treatment of painful, obstructive chronic pancreatitis failing conservative therapy [490,491]. Dite and colleagues [490] randomized 72 consecutive patients to surgery (80% resection and 20% drainage) or endotherapy (52% sphincterotomy and stenting or 23% stone removal). Aftert 5 years but not 1 year, patients had greater pain resolution (34% vs 15%) and weight gain (52% vs 27%) in surgical vs endoscopic groups. Drawbacks to this study are that only 50% of the eligible patients underwent random assignment, 50% were lost to follow-up, there was no true control group (no endoscopic or surgical intervention), and the pain pattern was not provided, which prevents characterization of patients' pain according to the clinically important descriptions by Ammann as "type A pain" or "type B pain."

The second randomized controlled trial by Cahen and colleagues [491] randomized 39 patients with severe pain and ductal obstruction to surgery (90% drainage or 10% combination drainage/resection) or endotherapy (sphincterotomy and stenting with or without stone removal), the latter following endoscopic shock-wave lithotripsy in 84% of patients (for stones > 7 mm). At 2 years, surgically drained patients had lower pain scores, greater pain relief (75% vs 32%) and higher quality of life scores ($P = 0.003$) compared with the endoscopic group. This study was particularly robust because few subjects were lost to follow-up (1/39) and there were multiple end points.

The two randomized controlled trials comparing endoscopic and surgical therapy indicate that surgical decompres-

sion has better long-term results than endoscopic techniques for treating pain and improving quality of life in patients with chronic pancreatitis and pancreatic ductal obstruction (strictures, stones, or dilation). Furthermore, both studies showed that endoscopic therapy had no greater effect on pain than the 38% endoscopic placebo response rate reported by others [492]. Surgery may be superior because surgery also reduces pancreatic tissue pressure, an endpoint that may predict the magnitude of pain resolution [493]. In contrast to a common misconception, pain relief was immediate (and not delayed) with surgery but was delayed with endoscopic decompression [491]. Importantly, these studies do not clarify whether surgical and endoscopic therapies differ for patients with type B pain but without pancreatic ductal strictures, stones, or dilation. Hence, for individual patients with painful, obstructive chronic pancreatitis, the decision to offer endoscopic, surgical or conservative treatment should be influenced by recognition that surgery has superior results compared with endoscopy, pain in most patients with chronic pancreatitis decreases over time, pain can recur in surgical groups [431] and in the presence of comorbidities, which may preclude surgical intervention. Finally, patients with type A pain should be managed with conservative medical treatment (no surgery or endotherapy) and those with refractory type B pain should be offered surgical therapy, except in select circumstances, particularly when surgery is contraindicated.

Endoscopic techniques also have been used for the removal of pancreatic stones in chronic pancreatitis. In different series, pancreatic duct stones were removed after endoscopic sphincterotomy in 27%–100% of patients [494,495]. In some cases, stone removal was facilitated by fragmentation with extracorporeal shock-wave lithotripsy, with clinical improvement observed in 50%–80% of cases in which the stones were successfully removed [495]. Inherent in these various therapies is the belief that stones are themselves causing symptoms by intensifying obstruction and that their removal will improve pancreatic flow and thereby reduce symptoms. On the other hand, it is also possible that pancreatic stones form as a result of pancreatic stricture and abnormal pancreatic juice protein and have little to do with pain. None of the studies on endoscopic treatment of chronic pancreatitis is controlled, and no valid comparisons have been made among medical, surgical, and endoscopic treatments. These procedures should therefore be considered experimental and performed only in patients entered into prospective, randomized trials.

In one study, minor papilla endoscopic sphincterotomy was performed in 52 patients with pancreas divisum who had chronic abdominal pain, acute recurrent pancreatitis, or chronic pancreatitis [496]. Among the three groups of patients, only those with acute recurrent pancreatitis benefited from the endoscopic procedure. This suggests that minor papilla sphincterotomy should be avoided in patients with pancreatic divisum and chronic pancreatitis.

Surgical treatment

After all medical measures have failed to relieve pain, surgery should be considered. The type of surgery is selected according to the perceived mechanism for the pain. When the main pancreatic duct is dilated, it is assumed that there is pancreatic duct obstruction and that pancreatic duct hypertension is the cause of the pain. On the other hand, if there is no ductal dilation, pain may result from diffuse parenchymal disease or blockage of small side ducts by stones, protein plugs, or scars. Relief of major duct obstruction should not affect this type of pain. Therefore, the type of surgery should be chosen according to the severity of pain, ductal morphology, and the extent of parenchymal disease. Patients who have ductal dilation have a 70%–80% chance of obtaining pain relief with either a partial resection with pancreaticojejunostomy or lateral pancreaticojejunostomy (modified Puestow procedure). The modified Puestow pancreaticojejunostomy is particularly suitable for patients who have ductal obstruction and dilation. It is a safe and effective operation, with a morbidity rate of less than 5%, mortality rate of less than 2%, and effective pain relief rate in the order of 80% [497,498]. On the other hand, for patients with moderate to severe parenchymal disease and no ductal dilation, partial pancreatic resection should be considered. Ninety-five percent distal resection is recommended for patients with diffuse parenchymal disease [433], whereas local resection of major site of involvement may be sufficient for those with regional parenchymal disease [433]. Overall, 50% of these patients have had satisfactory results.

Near-total pancreatectomy, or Whipple procedure, includes sacrificing portions of normal stomach and duodenum and can result in metabolic and digestive complications. To correct these problems, the original Whipple procedure underwent two subsequent procedural modifications. In 1978, Traverso and Longmire [499] described pylorus-preserving pancreatic duodenectomy, thereby avoiding the digestive complications of partial gastric resection. Several years later, Beger and associates [500] described a more conservative procedure that resected the diseased pancreatic head and preserved all extrapancreatic organs, including the duodenum (Fig. 69.11). A randomized trial comparing these two procedures in patients with painful chronic pancreatitis was performed [501]. There was no postoperative mortality, and morbidity was comparable in both groups (15%–20%). After 6 months of follow-up, patients who underwent duodenum-preserving pancreatic head resection (the Beger procedure) experienced less pain, better preservation of insulin secretion and glucose tolerance, and more stable weight than those who underwent a pylorus-preserving Whipple resection. This suggests clinical superiority of the Beger procedure as compared with the pylorus-preserving Whipple resection. However, the limited sample size and lack of long-term follow-up preclude any definitive conclusions.

In 1987, Frey and Smith [502] described another operation for painful chronic pancreatitis that consisted of local

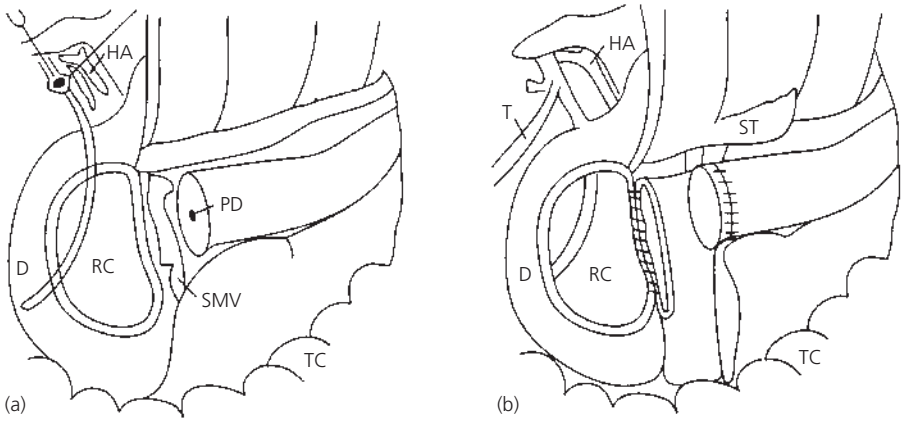

Figure 69.11 Duodenum-preserving resection of the pancreatic head as described by Beger. **(a)** A metal probe is inserted through the common bile duct into the duodenum to prevent inadvertent injury during resection of the pancreatic head. **(b)** Reconstruction includes an end-to-end pancreaticojejunostomy and a side-to-side anastomosis between the jejunum and the rim of the cavity remaining after resection of the pancreatic head. D, duodenum; HA, hepatic artery; PD, pancreatic duct; RC, resection cavity of the pancreatic head; SMV, superior mesenteric vein; ST, stomach; T, tube; TC, transverse colon. From Izbicki et al. [504], with permission from Lippincott Williams and Wilkins.

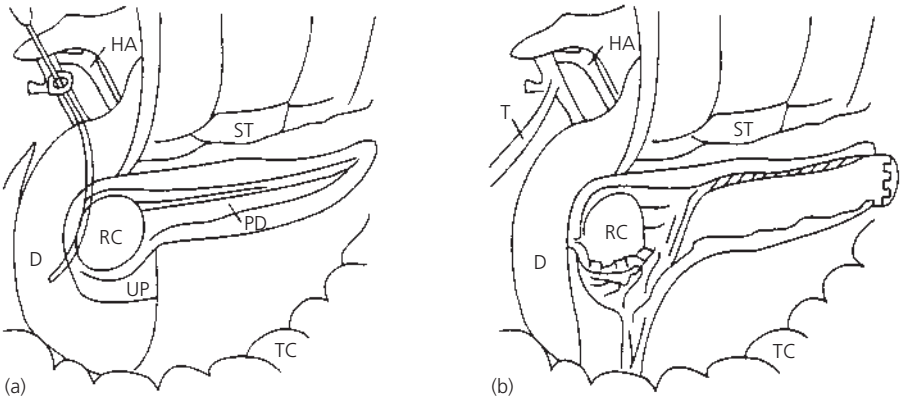

Figure 69.12 **(a)** Duodenum-preserving resection of the pancreatic head as described by Frey. A metal probe is inserted through a choledochotomy into the duodenum before resecting the pancreatic head mass to minimize the risk for bile duct injury. **(b)** Reconstruction consists of a side-to-side pancreaticojejunostomy including the resection cavity of the pancreatic head. [504], with permission from Lippincott Williams and Wilkins.

resection of the pancreatic head combined with longitudinal pancreaticojejunostomy (Fig. 69.12). This procedure was designed to improve decompression of the head of the pancreas, which often was not drained well by conventional pancreaticojejunostomy. Frey and Amikura [503] reported their results in 50 patients with chronic pancreatitis in a 7-year follow-up study. There were no operative deaths, and 22% of patients developed postoperative complications. Pain relief was complete or pain was improved in 87% of patients. Twenty percent of patients developed new-onset postoperative diabetes, and 11% experienced worsening of their diabetes.

The two techniques of duodenum-preserving resection of the pancreatic head (the Beger and Frey procedures) were compared in a prospective study [504]. There was no operative mortality in both groups, and postoperative morbidity was significantly lower in patients who had undergone the Frey procedure, which is technically less demanding. Both groups of patients reported similar postoperative decreases in pain and improved quality of life index scores. Postoperative pancreatic endocrine and exocrine function was also similar in both groups. These results are encouraging, but the mean follow-up of 1.5 years is relatively short. Long-term studies are needed to determine whether either or both procedures will suffer from attrition of the initial good results. It should also be noted that the duodenum-preserving resections are not appropriate for all patients with symptomatic chronic pancreatitis but seem especially useful for patients with predominant involvement of the pancreatic head.

Nealon and Matin [505] evaluated the success rates of different surgical procedures in relieving both the chronic abdominal pain and the recurrent exacerbations associated with chronic pancreatitis. Patients were divided into three groups based on the characteristics of their pain: severe unrelenting pain alone, severe pain with intermittent acute exacerbations, and intermittent acute exacerbations only. Postoperative pain relief was achieved in 83% of patients overall, with 86% relief from lateral pancreaticojejunostomy, 67% from distal pancreatectomy, and 91% from pancreatic head resection. It appears that pancreatic head resection was most effective for the relief of chronic pain (91%), whereas distal pancreatectomy was least effective (67%). On the other hand, lateral pancreaticojejunostomy gave the best relief of acute pain exacerbations (91%), whereas distal pancreatectomy was rather ineffective (33%). Pancreatic head resection was much more effective in reliev-

ing chronic pain (91%) than pain related to acute exacerbations (58%). These observations suggest that stratification of patients according to their pain patterns may be helpful to select the most effective surgical procedure for pain relief.

In patients undergoing a near-total pancreatectomy, islet cell autotransplantation by infusion of islet cell preparations into the portal system may prevent diabetes [506–508]. Islets from the resected pancreas can be isolated by mechanical disruption and collagenase digestion of the dispersed tissue and injected into the portal vein. Using this method, Farney and colleagues [508] reported that 9 of 22 patients with intraportal islet autografts were insulin independent for at least several months after surgery. Wahoff and associates [509] reported long-term insulin independence in 33% of 48 patients who underwent pancreatic resection combined with islet autotransplantation and followed up for 2–10 years. Insulin independence after islet autotransplantation correlated most closely with the number of islets transplanted and therefore relates to the available mass of pancreatic tissue and the degree of pancreatic fibrosis. Of those patients who received fewer than 200 000 islets, only 22% achieved long-term insulin independence. By comparison, nearly 60% of patients who received more than 300 000 islets achieved long-term independence.

With recent advances in islet isolation techniques, there appears to be an overall improvement of the results of islet autotransplantation. Recent studies indicate that about 50% of patients undergoing total or subtotal pancreatectomy can become insulin independent after intraportal autologous islet transplantation [510,511]. In the largest published series of 43 patients undergoing total or near-total pancreatectomy for chronic pancreatitis, insulin independence persisted in 34% of patients 2–10 years after surgery, and no graft failure occurred after 2 years [509]. Patient selection is important to determine the success of islet cell autotransplantation on diabetes after total pancreatectomy for chronic pancreatitis. Patients with end-stage fibrotic glands and those who are narcotic-dependent are unlikely to do well postoperatively [511].

Summary of treatment approach for control of pain

We recommend the following approach to treat the pain of chronic pancreatitis. When a patient first presents with pain or shows a different pain pattern, we determine whether there is an anatomical reason for the occurrence of pain or a change in pain. Pseudocyst, phlegmon, obstruction, and peptic ulcer are ruled out by appropriate tests. Patients are advised to stop all alcohol ingestion and to use salicylate or acetaminophen as needed. We also recommend the use of enzyme (e.g., 8 tablets of Viokase with each meal), especially in patients with non-alcohol-induced chronic pancreatitis. If pain continues, a trial of octreotide may be considered. After all medical measures have failed, a number of selected patients may benefit from pancreatic duct stenting and for others we recommend surgery; some centers, however, may consider celiac plexus block before surgery (Fig. 69.13).

Management of pancreatic insufficiency

At first glance, treating malabsorption secondary to pancreatic insufficiency might appear to be relatively easy. It would seem that simple oral replacement of pancreatic enzymes would be efficacious. Unfortunately, complete correction of steatorrhea is rarely accomplished. This is related to insufficient amounts of enzyme in oral supplements and acid pepsin inactivation of pancreatic enzymes.

The maximal postprandial delivery of pancreatic lipase is about 140 000 IU/h for 4 h after meals [270]. It has been shown that malabsorption does not occur if more than 5% of the normal maximal enzyme output is delivered to the duodenum. To meet this requirement, 28 000 IU of lipase should be delivered during a 4-h postprandial period. Pancreatic supplements are highly variable in enzyme activity, with lipase content ranging from 0 to 8000 IU per tablet [313,512,513]. Therefore, if the clinician uses a commercially available preparation containing 3500 IU per tablet of lipase, then under the best of circumstances, at least 8 tablets or capsules must be taken per meal to abolish malabsorption. Smaller amounts of enzymes may reduce steatorrhea but not abolish it. Therefore, the clinician should choose those commercial enzyme preparations that have been shown to contain higher lipase activity, and ensure that sufficient amounts have been used (Table 69.8).

Another important factor to consider is acid peptic inactivation of pancreatic enzymes. When duodenal samples were examined for lipase and trypsin activity, less than 8% of ingested lipase and less than 22% of ingested trypsin was recovered, regardless of the dosing schedule used (either prandial or hourly dosing). To eliminate steatorrhea in pancreatic insufficiency, a large number of tablets are necessary. Hyperuricosuria [514] and kidney stones have been associated with such high dosing of pancreatic supplements secondary to their high purine content, and therefore, this high dosing schedule may not be clinically justified. The relatively low delivery of lipase into the proximal small bowel compared with the delivery of trypsin with routine treatment schedules may explain the relative impossibility of completely correcting steatorrhea in pancreatic insufficiency as well as the usual correction of azotorrhea.

Preventing acid peptic neutralization of enzyme supplements by coating the capsules with acid-resistant and alkali-sensitive materials or by using antacids has produced mixed results [515,516]. In most studies, there has been little success with oral antacids or enteric coating with regard to clinical improvement or alleviating steatorrhea. Antacids increase gastric secretion, and dilution of enzyme concentrations below critical levels may explain the relative ineffectiveness of antacids [516]. Enteric coating is effective only if

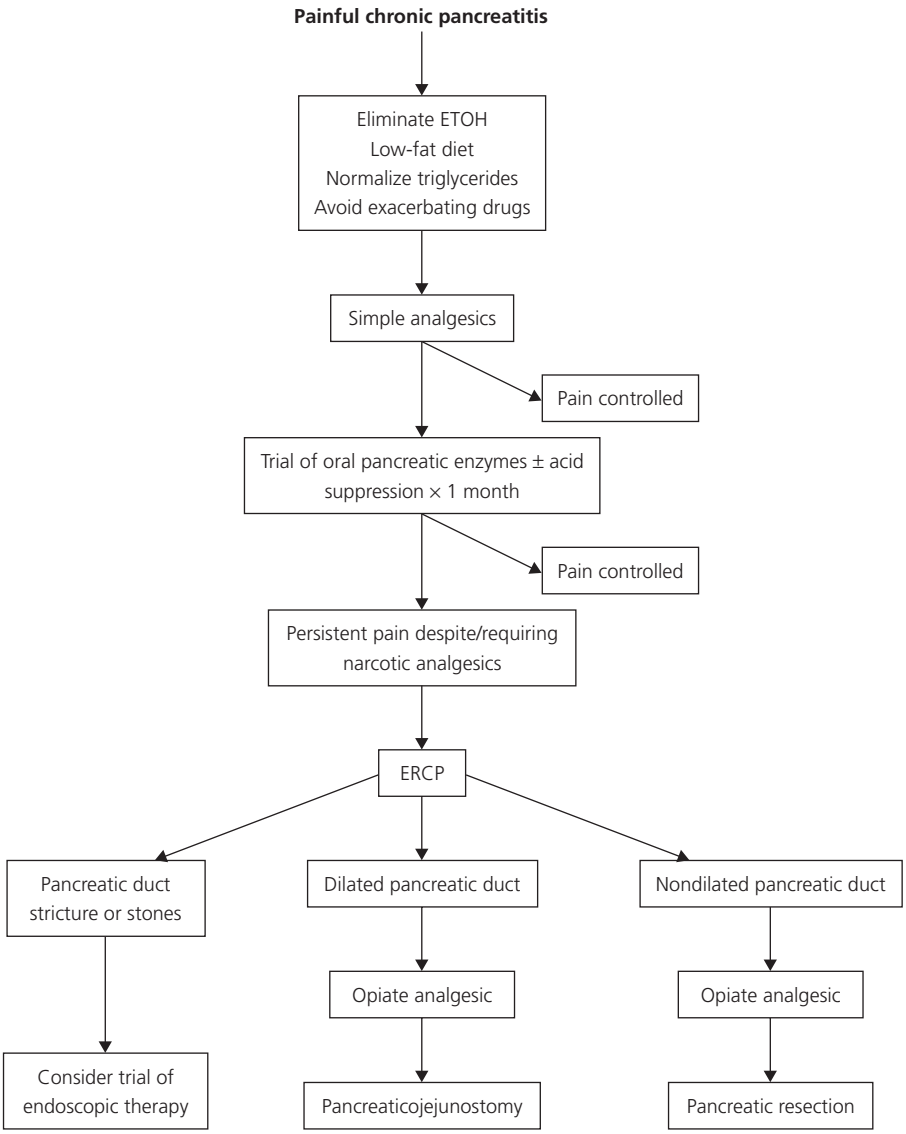

Figure 69.13 Algorithm for management of the patient with painful chronic pancreatitis. ERCP, endoscopic retrograde cholangiopancreatography; ETOH, methyl alcohol.

pancreatic enzymes are delivered into the duodenum with ingested food from the stomach and adequate intraduodenal dissolution occurs. Emptying of large tablets from the stomach may be different from that of typical antral contents, and duodenal and gastric pH have been shown to be low (pH < 4.0) for prolonged periods in many patients with pancreatic insufficiency [314,517], so enteric coating may not be an effective improvement over oral pancreatic supplements alone.

Pancrease (pancreatin coated with a pH-dependent polymer) is another improvement in pancreatic enzyme supplements [518]. This supplement is stable at an acidic pH (pH < 4.0) and dissolves at a pH greater than 5.0 so it is most effective (i.e., better than standard tablets alone) in patients who maintain acidic pH levels in the stomach postprandially. This maneuver delivers pancreatic enzymes to the upper small bowel intact, whereas standard supplements are irreversibly inactivated. In several studies, the mean reduction of steatorrhea with the use of Pancrease is not better than that with Viokase given with meals [516,519]. Normally, in chronic pancreatitis, the gastric pH increases to above 5.0 in the early postprandial period and then decreases to less than 4.0. It is likely that, under these circumstances, pancreatin initially will be liberated from its enteric coat, but its enzyme activity will be irreversibly inactivated when the intragastric pH falls to less than 4.0. Conversely, if gastric and duodenal pH remain low (pH < 4.0) throughout the postprandial period [520], the enteric coat of Pancrease remains intact as it traverses the upper gastrointestinal tract, and pancreatin is liberated en masse only as it reaches the jejunum, where intraluminal pH is greater than 5.0. This may explain the effectiveness of Pancrease in abolishing steatorrhea in some patients who secrete more acid and presumably can maintain an acidified upper small intestine for a prolonged period of time.

Table 69.8 Commercial pancreatic enzyme preparations

Preparation	Type	Content (Units)		
		Lipase	Amylase	Protease
Cotazyme	C	8000	30 000	30 000
Cotazyme-S	ECMS	5000	20 000	20 000
Creon 10	ECMS	10 000	33 200	37 500
Creon 25	ECMS	25 000	74 700	62 500
Ilozyme	UCT	11 000	30 000	30 000
Ku-zyme HP	ECMS	8000	30 000	30 000
Pancrease	ECMS	4000	20 000	25 000
Pancrease MT-4	ECMT	4000	12 000	12 000
Pancrease MT-10	ECMT	10 000	30 000	30 000
Pancrease MT-16	ECMT	16 000	48 000	48 000
Protilase	ECMS	4000	20 000	25 000
Viokase	UCT	8000	30 000	30 000
Viokase	P	16 800	70 000	70 000

C, capsule; ECMS, enteric-coated microspheres encased in a cellulose capsule; ECMT, enteric-coated microtablets encased in a cellulose capsule; P, powder; UCT, uncoated tablet.

Until recently, the major criterion for determining the efficacy of enteric-coated enzyme preparations was the size of the microspheres, which influences the timing of enzyme delivery to the intestine. It has been shown that microspheres with a diameter of about 1.4 mm appear to mix with chyme most thoroughly and are emptied from the stomach at the same rate as food; large spheres remain in the stomach after food has been emptied into the small bowel and are less effective in correcting malabsorption in chronic pancreatitis [521]. Some commercially marketed microspheres (more than 2 mm) of pancreatin empty too slowly to be effective in the digestion of food. This may explain why some enteric-coated preparations are not effective in correcting pancreatic steatorrhea. However, a recent prospective, randomized, double-blind, multicenter, crossover trial in patients with chronic pancreatitis who have a stool fat excretion of 7.5 g/day showed that there was no difference between Creon given as microspheres with a diameter of 1–2 mm and as mini-microspheres with a diameter of 0.7–1.6 mm [522]. The mean stool fat excretion per day was about 16 g in both groups. Reducing microsphere size does not therefore improve the efficacy of the enzyme supplements. An explanation for this observation may be that microspheres aggregate in vivo into larger particles in the presence of free oil [523]. It should be noted that high doses of pancreatic enzyme supplements in children with cystic fibrosis have been associated with recurrent bowel obstruction as a result of fibrosing colonopathy, characterized by dense submucosal fibrosis in the large bowel. In recent years, two cases of fibrosing colonopathy have been reported in adult patients, one with and one without cystic fibrosis [524,525]. The cause of fibrosing colonopathy associated with high doses of pancreatins remains speculative [526].

Histamine H_2 receptor antagonists decrease acid production, pepsin activity, and gastric secretory volume simultaneously and should optimize pancreatic enzyme concentrations [516,527]. Duodenal lipase and trypsin activities are consistently increased with concomitant Viokase and histamine H_2 receptor antagonist treatment. Cimetidine should be considered only in patients who do not respond to standard oral pancreatic supplements because of lifelong increased cost and potential unknown long-term side effects. It has been shown that omeprazole further reduces fecal fat excretion in patients with cystic fibrosis receiving enzyme replacement for pancreatic insufficiency [528]. Therefore, in patients in whom histamine H_2 receptor antagonist fails to abolish steatorrhea, use of omeprazole should be considered.

We recommend the following approach to treat patients with pancreatic insufficiency. It is critical that sufficient amounts of enzyme tablets be given (e.g., 8 tablets of Viokase with each meal) to abolish azotorrhea and significantly reduce steatorrhea. Most patients on this regimen achieve satisfactory nutritional status and become relatively asymptomatic. In some of the symptomatic patients, the number of tablets given prandially can be increased or the amount of dietary fat can be reduced. These measures usually are effective in alleviating symptoms. In occasional patients, the use of Pancrease may be necessary. The addition of a histamine H_2 receptor antagonist or omeprazole should be reserved for those patients who are resistant to these maneuvers and who have documented acidic duodenal pH levels, because of cost considerations as well as potential long-term side effects. If all of these measures are ineffective, documentation of diagnosis (by pancreatic function testing) and exclusion of other contributing causes (celiac sprue, terminal ileal disease, or bacterial overgrowth) must be carried out.

Management of pancreatic diabetes

Clinical diabetes occurs relatively late in the disease and is an independent predictor of mortality of chronic pancreatitis. Ketoacidosis and diabetic neuropathy were relatively uncommon in this form of diabetes. This is probably because in pancreatic diabetes, insulin secretion is not completely lost, and glucagon secretion is reduced. Although some patients may respond to oral hypoglycemics, insulin is needed in most patients. Insulin requirements are usually lower than for most patients with genetic diabetes because insulin receptors usually are not down-regulated and insulin antibodies initially are not present. Overzealous control of blood glucose should be avoided because this may result in life-threatening hypoglycemia.
